

# **Seismic Interpretation Principles and Workflow**

H. Roice Nelson, Jr.

# Day 2 Session 3

- Structural interpretation
  - Fault interpretation
  - Fracture interpretation
  - Anisotropy interpretation
- Stratigraphic interpretation
  - Sequence interpretation
    - Divergent
    - Convergent (thinning)
    - Parallel
    - Semi Layer-Cake to Layer Cake
    - Chaotic
  - Geochronostratigraphic reconstruction
- Integrating other data into the interpretation
- Salt and fault shadow interpretation
- Exploration interpretation
- Reservoir characterization
- Project Documentation
- Display Concepts and Interpretation Procedures

# Structural Styles Chart

# Drag Folds on Thrust Faults

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

DRAG Folds on THRUST FAULTS are due to friction along low angle reverse faults. Drag Fold form below and above thrust faults and on the back flank of the thrust block as illustrated below.

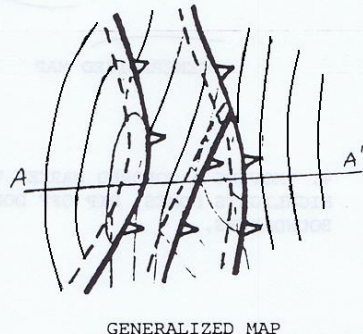

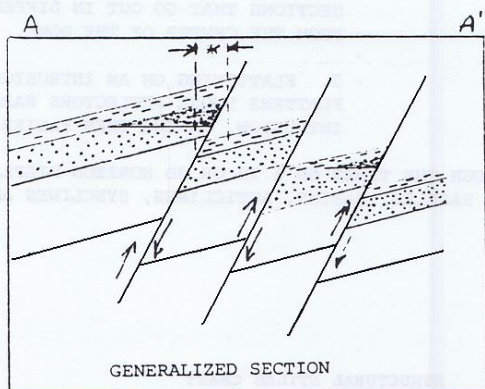

The Interactive environment can aid interpretation of these types of structures by allowing the interpreter to:

1. Add a constant to an upper horizon to look for subtle back flank drag folds. An example of this type of structure is the Brady Unit in Sweetwater County, WY.
2. Flatten on a continuous upper horizon, which tends to enhance reflectors with less continuity closer to the fault zone. The Anschutz Ranch Field is an example.
3. Do iterative ray trace modeling and side by side or overlaid comparison of synthetic and stacked sections gives much more confidence of this type of structure.
4. Select sections along arbitrary lines from a 3D data volume, which are orthogonal to the strike of the fault in order to show the faulting better.
5. Map displays of the entire extent of a horizon using shadow horizon(s). See point 3 of REVERSE FAULT TRAPS.

# Reverse Fault Traps

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

REVERSE FAULT TRAPS are due to compressional forces. In order to form traps, the faults must cut dipping rocks and be curved or at the junction of two faults. Offshore California has several major fields with these type of complicated structures.

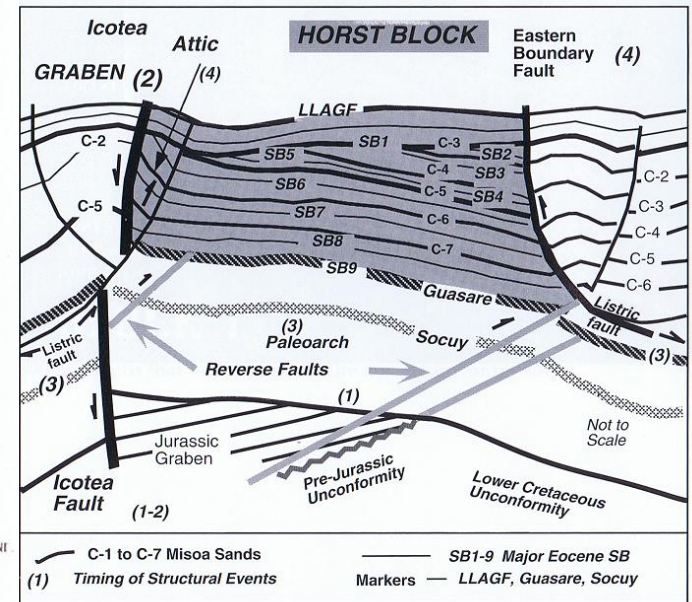

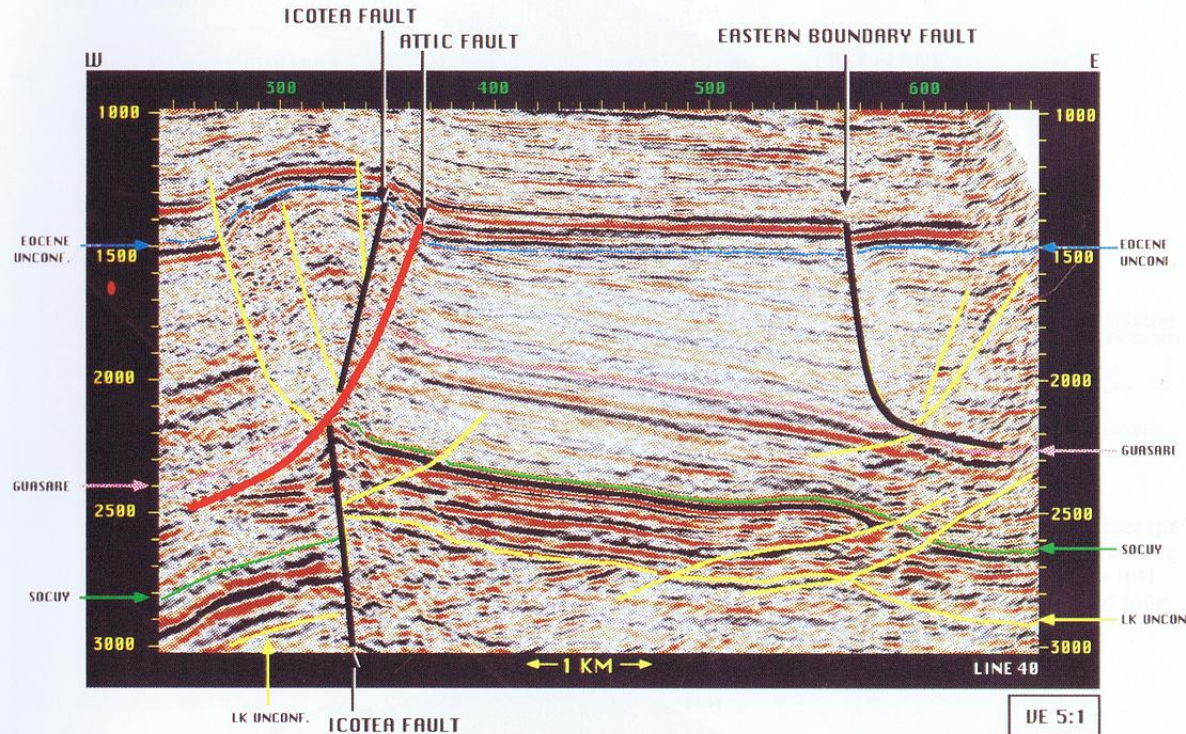

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Enhance fault cuts by changing the seismic display scales. Shrinking the horizontal scale by decimation of seismic traces makes the faults more vertical, enhancing breaks in the reflectors.
2. Reconstruct pre-fault structure using the polygon fault correlation window.
3. Build map displays that show the entire extent of a horizon. Note most mapping packages contour single valued surfaces. Ith the workstation, shadow horizon(s) can be interpreted under thrust blocks (\*) and displayed as contours over a 3D survey's density map display.

Martin H. Link, et. al. in **Application of 3-D Seismic Data to Exploration and Production**, pages 74, 76, data from Maraven from Central Lake Maracaibo, Venezuela.

# Igneous, Salt, and Shale Domes

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

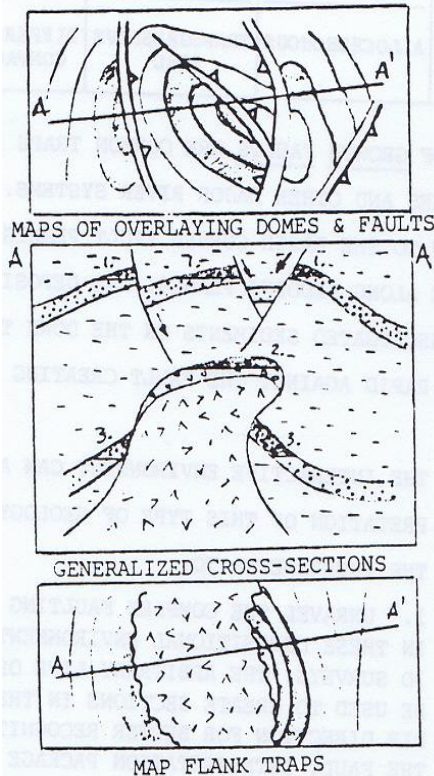

IGNEOUS, SALT and SHALE DOMES are a result of intrusions, either volcanic in origin or gravity induced movement of low density materials. Domes, circular or elliptical anticlines, are one of the most widespread types of hydrocarbon traps.

The Interactive environment can aid interpretation of dome type structures by allowing the interpreter to:

1. Easily select sections to best evaluate critical closure on the flank of the structure. Dip sections are retrieved from a 3D survey using the arbitrary line option. For 2D surveys, those portions of the 2D lines zigzagging across the structure are easily retrieved without finding and folding paper sections.
2. Once a possible dome is located, it can be easily confirmed by selecting several sections that go out in different directions from the center of the dome.
3. Flattening on an intrusion horizon also flattens those reflectors parallel to the intrusion, making them easier to see.
4. Moving a colored marker through the times on a 3D or 3D horizon display dramatically highlights domes, dip off domes, saddles, basins, anticlines, synclines and fault boundaries.

# Salt Domes

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

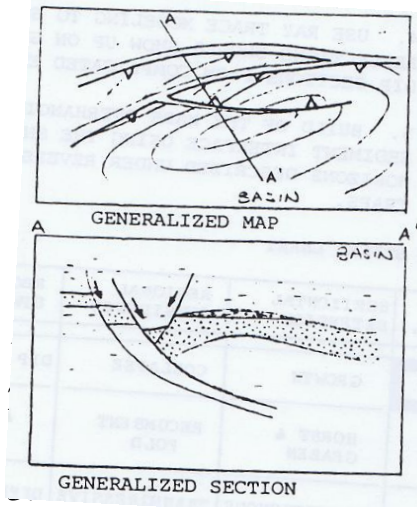

SALT DOMES, particularly, have additional traps, which are due to a combination of structure and stratigraphy. These traps include (1) overlaying domes and faults, (2) strat traps, and (3) flank traps. Uplifted overlaying sediments often form traps, which can be faulted separating the reservoirs into numerous pools. Fractures and vugs in the cap rock create reservoir rock. Flank traps tend to have thick pay zones due to dip. The Interactive environment can aid interpretation of salt dome by allowing:

1. Rapid building and revising surfaces to test the location of the salt-sediment interface and to study fault patterns.
2. Use the polygonal drag window to correlate horizons across fault blocks and on different sides of the dome.
3. Flatten horizons to study pre-salt or pre-fault depositional patterns and to reconstruct the depositional and tectonic history.
4. Use ray trace modeling to study where reflections should show up on specific dip sections from complicated events.
5. Build maps of overhanging salt-sediment interface using the shadow horizons described under reverse fault traps.

# Annealment Structures

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

ANNEALMENT STRUCTURES on the downthrown side of GROWTH FAULTS are common traps at the mouths of major river systems. At depth movement of curved fault planes often starts along bedding planes, with rapid growth against the fault, creating broad anticlines on the basin side.

The Interactive environment can aid interpretation of these types of geology by allowing the interpreter to:

1. Unravel the complex faulting occurring in these depositional environments. With 3D surveys, the arbitrary line can be used to create sections in the fault dip direction for better recognition. The fault interpretation package can be used to pick faults on a few critical 2D or 3D sections, labeling the same fault from map displays, build fault plane surfaces, evaluate with map or 3D displays, and bring up other sections cutting the fault plane to check and modify fault locations.
2. Make drag windows with different vertical scales and use these to correlate similar rock layers across the growth faults.
3. Flatten on key horizons keeping growth consistent within different fault blocks.
4. Build map displays showing the structure of a key horizon overlain with an isochron contour map to evaluate growth or expected trap closure.
5. Tie in modeling results, well log synthetics, and VSP data to confirm the interpretation.

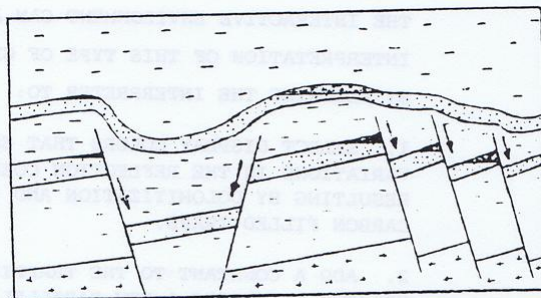

# Tilted Fault Blocks

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

TILTED FAULT BLOCKS are large, structural blocks, often miles across, broken and tilted by normal faulting. These large structures are formed in areas of rifting like the North Sea, Andaman Sea, Labrador Sea, and U.S. Great Basin, and when covered with sediments, can form giant fields.

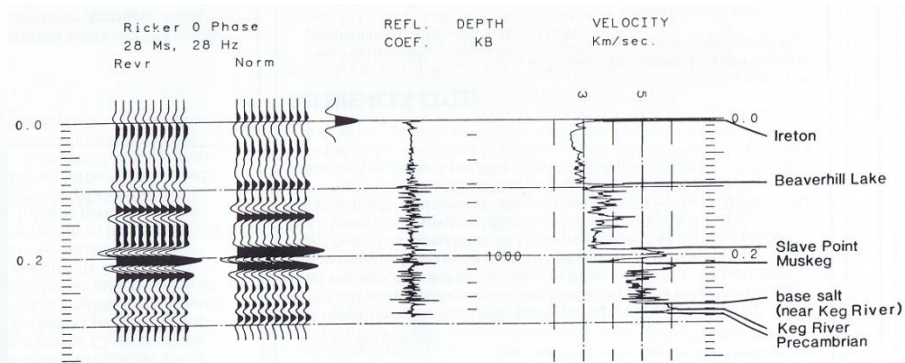

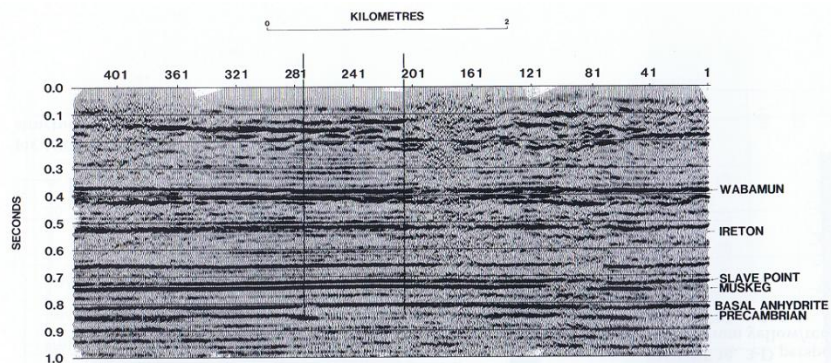

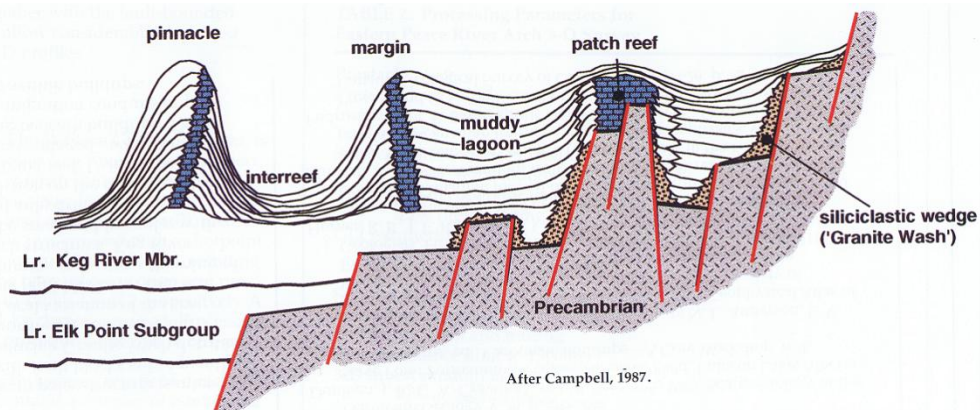

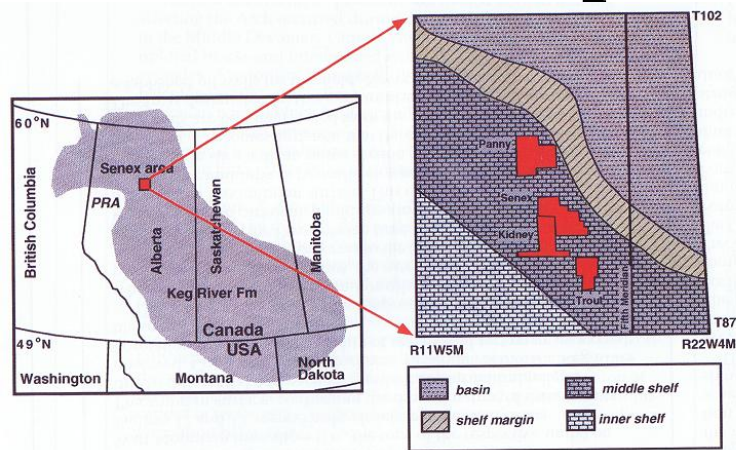

The Interactive environment can aid interpretation of this type of geology by allowing the interpreter to:

1. Overview 30 KM regional lines by rescaling.
2. Use trace and sample interpolation to allow detailed analysis of anomalies, including wiggle trace evaluation of the waveform variations.
3. Enhance fault cuts by changing the display scale. The more vertical the faults are made by stretching the vertical scale or shrinking the horizontal scale, the more the breaks in continuity are enhanced.
4. Choose the proper color assignment for the seismic display to enhance no data areas due to faulting, as well as reflection continuity and similar reflection sequences across faults.
5. Use horizon computations to create a new horizon by adding a constant to a picked horizon, which can create seed horizons through no reflection areas which can be easily adjusted by changing the picking options.

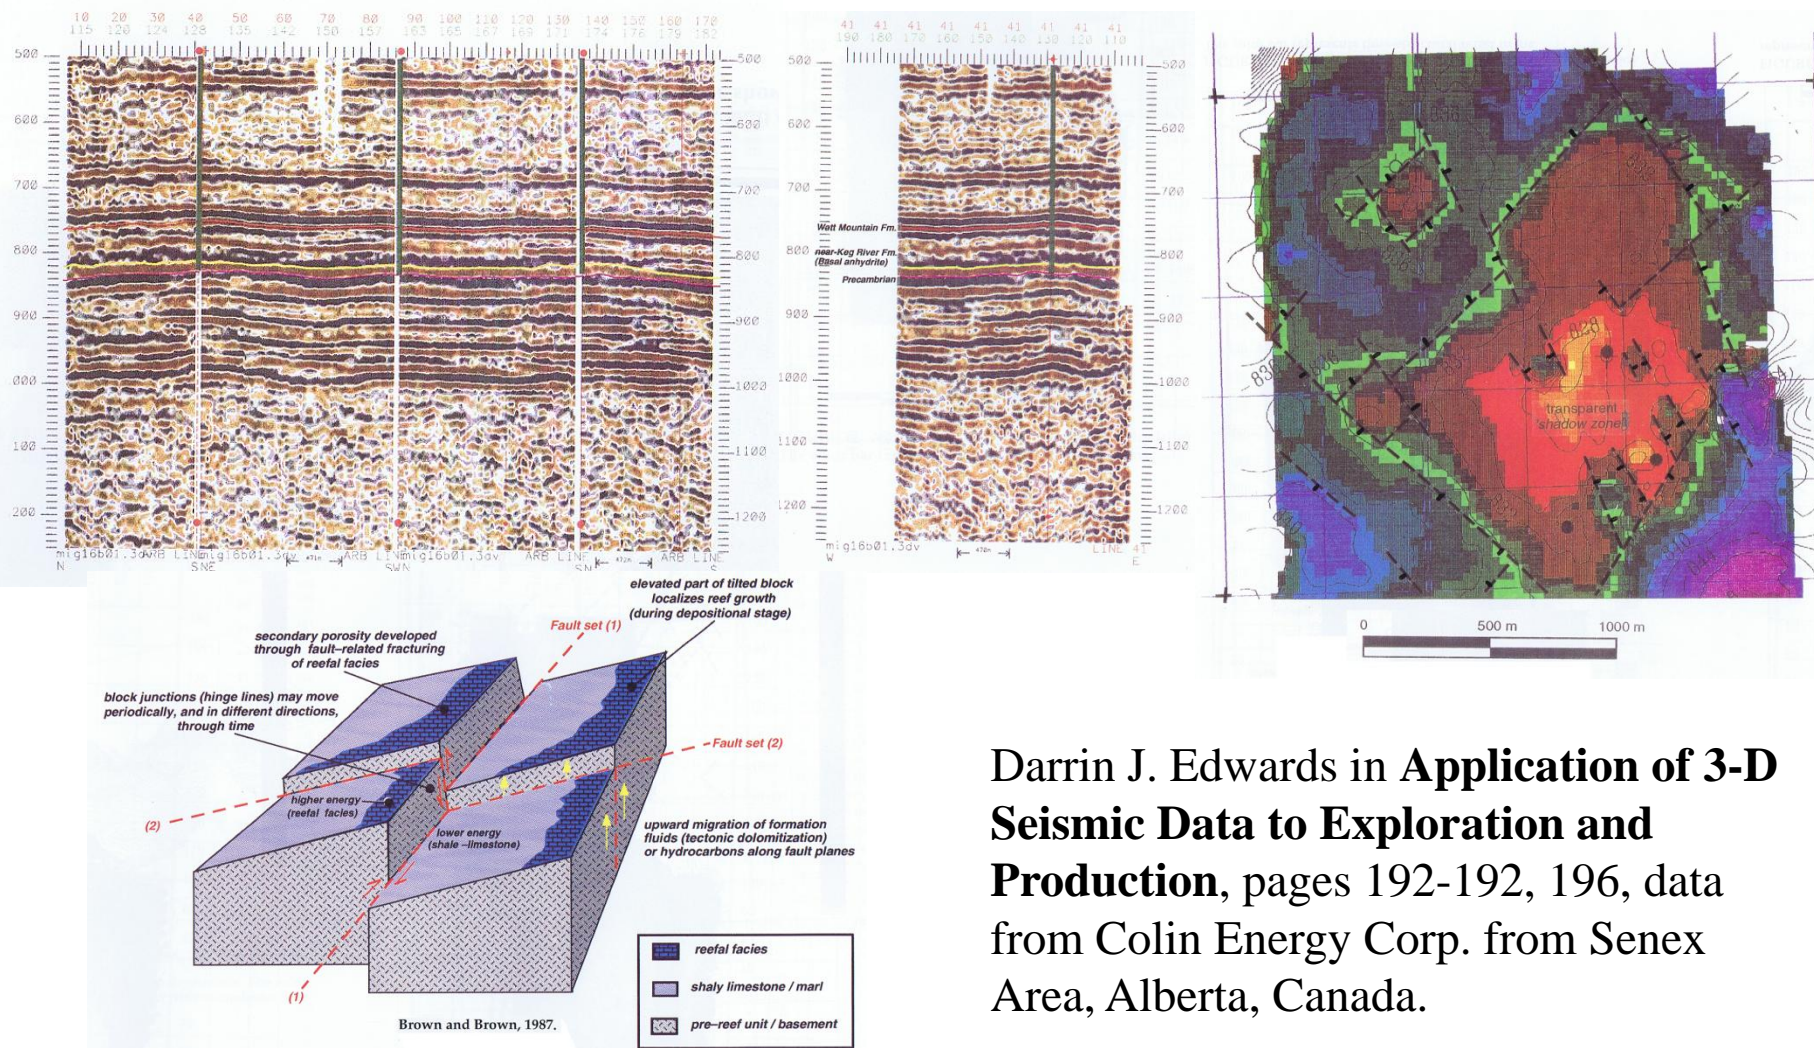

GENERALIZED CROSS-SECTIONS

# Tectonic Controls on Devonian Reef Development, Alberta, Canada

Darrin J. Edwards in **Application of 3-D Seismic Data to Exploration and Production**, pages 192-192, 196, data from Colin Energy Corp. from Senex Area, Alberta, Canada.

# Tectonic Controls on Devonian Reef Development, Alberta, Canada

Darrin J. Edwards in **Application of 3-D Seismic Data to Exploration and Production**, pages 192-192, 196, data from Colin Energy Corp. from Senex Area, Alberta, Canada.

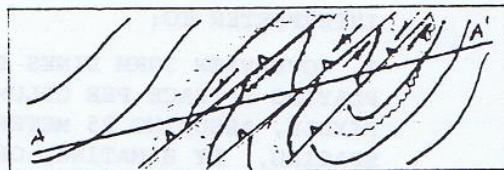

# Secondary or Tectonic Dolomite

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

SECONDARY or TECTONIC DOLOMITE traps are typically the result of water percolating along fractures turning impermeable limestone into dolomite. The stratigraphic changes typically follow the orientation of the fractures, forming fault controlled combination traps. Examples are the oil fields that started production in the late 1880's near Findley, Ohio, and the giant Arun gas field in Sumatra.

The Interactive environment can aid interpretation of this type of geology by allowing the interpreter to:

1. Select display colors to enhance variations in the reflection coefficient resulting from dolomitization and hydrocarbon filled traps.
2. Add a constant to the trapping horizon, creating a parallel horizon at a reflector within the limestone layer showing where there has been velocity induced distortions to the layer.
3. Build fault maps to determine expected areal extent and trends of dolomitization.
4. Extract seismic reflection amplitudes at horizons where there are amplitude variations associated with hydrocarbons and display the results on 2D or 3D map displays to see the areal extent of variations.
5. Make animation files to study subtle changes in amplitude, reflection character, reflector dip, or fault trends.

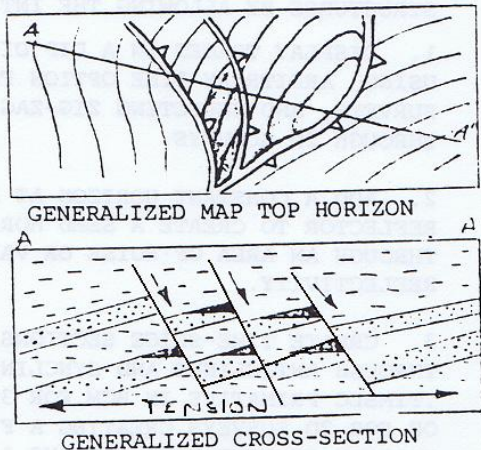

# Normal Fault Traps

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

NORMAL FAULT TRAPS are structural traps resulting from tectonic forces. To form hydrocarbon traps, faults must cut dipping rocks and must either be curved or at the junction of two faults.

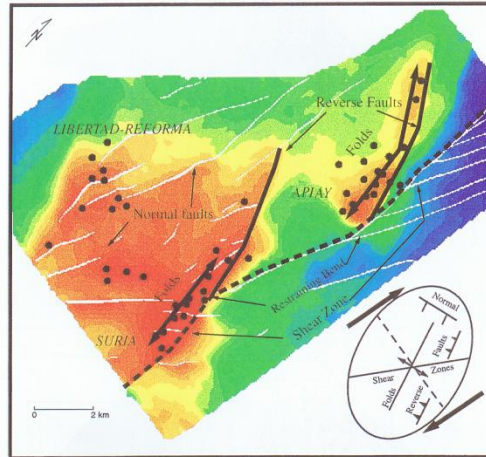

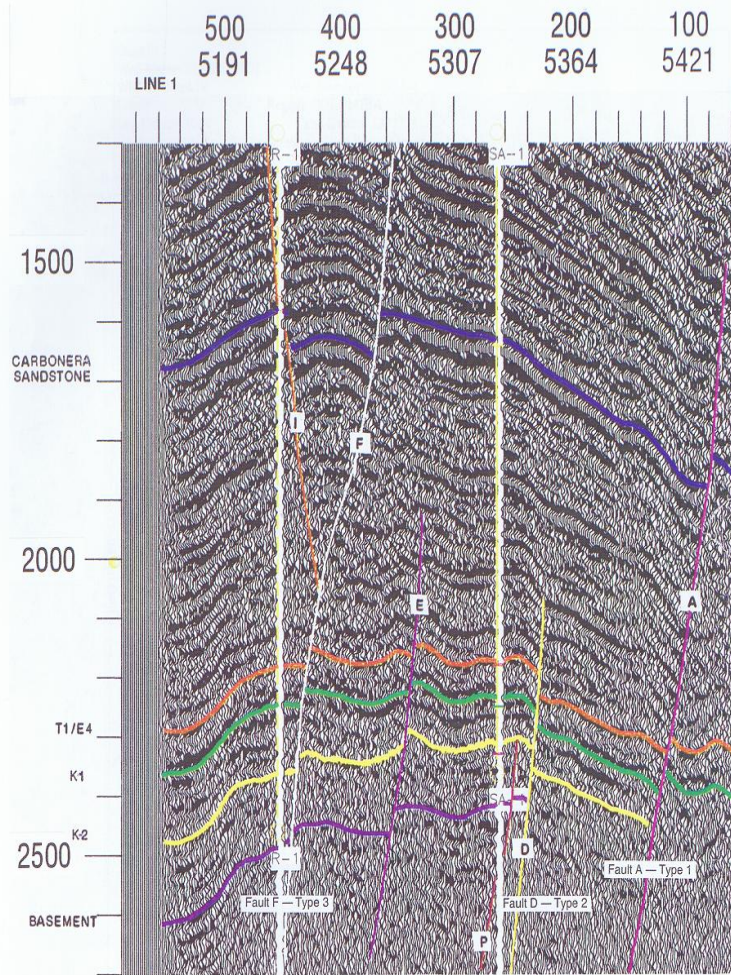

Normal faults are associated with domes, growth basins, and other tensional tectonic movements.

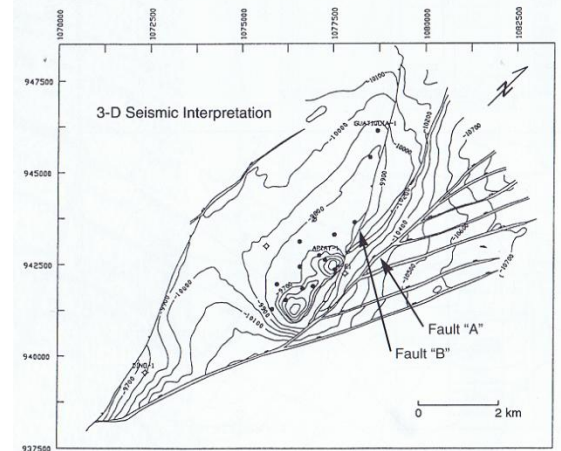

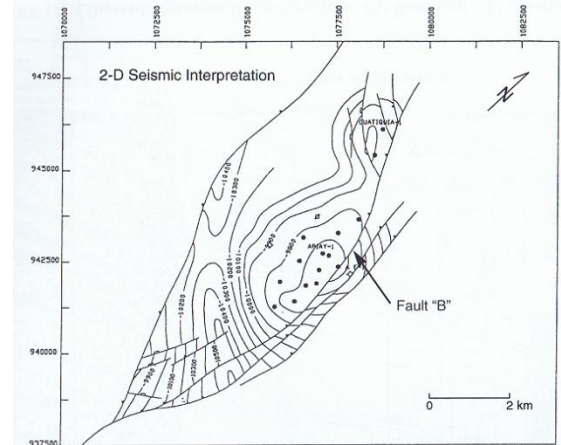

The Interactive environment can aid the interpretation of these types of structures by allowing the interpreter to:

1. Use the polygonal fault correlation window to reconstruct geology prior to faulting.
2. Build fault plane maps to understand complex fault trends.
3. Instantly enhance reflection continuity by adjusting the color look-up tables to give an AGC appearance to the seismic data.
4. Instantly change the color look-up tables to enhance strong amplitude events (bright spots), reverse the apparent polarity, or coloring specific amplitude ranges associated with sands or interest yellow while decreasing other amplitudes.
5. Flatten seismic relative to horizon picks. If picks are not made down fault scarps, there will be gaps in the flattened seismic section showing the trace location of faults at the horizons used for flattening.
6. Reconstruct the fault history by building picture or animation files of seismic data flattened starting with deep horizons and moving up through depositional history. These steps can be tied to hydrocarbon migration times.

# 2-D vs. 3-D Structural Interpretation

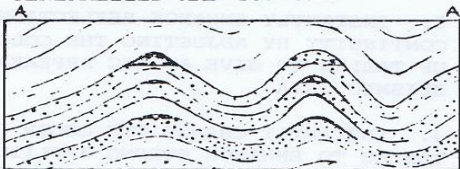

Mario Gutierrez, et. al.  
in **Application of 3-D  
Seismic Data to  
Exploration and  
Production**, pages 64-  
65, data from  
Ecopetrol from Llanos  
Basin, Columbia.

# Anticlines

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

ANTICLINES are large, upward arches often formed in areas of compression. These structures can have multiple producing zones. Anticlines are found with many different types of structural styles and are widely distributed geographically as hydrocarbon traps. Typical examples are found in the Oklahoma Mountains, which consist of elongated domes of basement rock.

The Interactive environment can aid the interpretation of these types of structures by allowing the interpreter to:

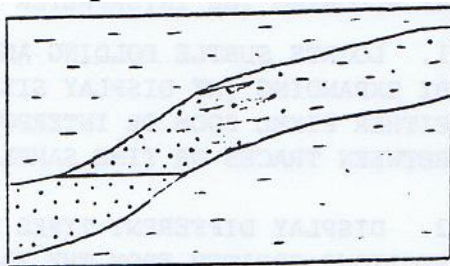

1. Display traces in a dip direction using arbitrary line options for 3-D surveys and zig-zag lines through 2-D surveys.
2. Add a constant horizon at a good reflector to create a seed horizon through an area of noise or variable reflectivity.
3. Create time-slice sections to step through anticlines and synclines. For a 2-D survey create a flat horizon at time zero, add (a) constant(s) to the times or horizons of interest and extract 2-D time-slices or horizon slices.
4. Look at animations through 3-D time-slice files for detail study of structure expansion (anticlines), linear trends (faults), subtle patterns in noisy data, and horizon crossing events that can be related to hydrocarbon / water contacts, saddle points, etc.
5. Reconstruct paleogeology by flattening vertical sections to specific horizons or by making horizon-slices.
6. Work with horizon map displays to do detailed evaluation of anomalies and guide the sections to display next.

# Updip Facies Changes

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

UPDIP FACIES CHANGES form combination traps when the reservoir rock is porous and permeable downdip and changes to an impermeable facies in the updip direction. These reservoirs would be classified stratigraphic if sands were deposited downdip and shales updip during the same geologic sequence, but structural if the impermeable facies were due to later uplift. These traps tend to form small fields.

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

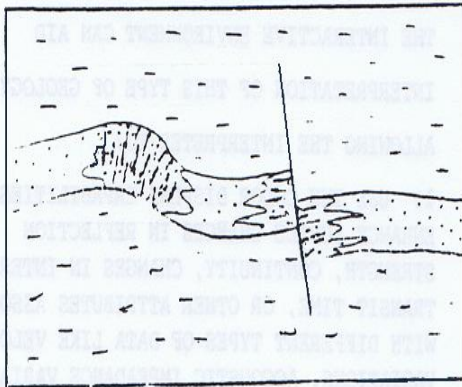

GENERALIZED CROSS-SECTION

1. Use the color display capabilities to enhance subtle changes in reflection strength, continuity, changes in interval transit time, or other attributes associated with different types of data like velocity variations, acoustic impedance variations, etc.
2. Flatten seismic relative to specified horizons to reconstruct geologic history and determine the depositional environment and whether an anomaly is structurally or stratigraphically controlled.
3. Extract attributes at and parallel to a horizon to look for spatial variations which can be related to.
4. Work back and forth between map and section displays to quickly and accurately determine the spatial size, orientation, and relationship between anomalies.
5. Look for anomalies which can be related to hydrocarbons; like flat gas/water contacts, gas induced velocity pushdowns, bright spots or dim spots, etc.

# Fractured Reservoirs

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
<b>Detached</b>	Thrust	Domes	Growth	Collapse	Dip & Fault
<b>Involved</b>	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
<b>Weak</b>	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

FRACTURED RESERVOIRS occur in fine grained rocks that have some porosity but need additional porosity and permeability to be hydrocarbon reservoirs. These rocks can produce hydrocarbons from fractures caused by folding or faulting. The Austin Chalk plays in Central Texas and many of the new resource plays are examples of this type of structural trap.

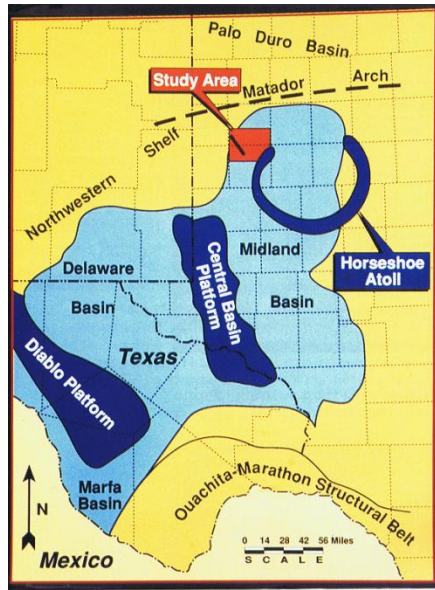

GENERALIZED CROSS-SECTION

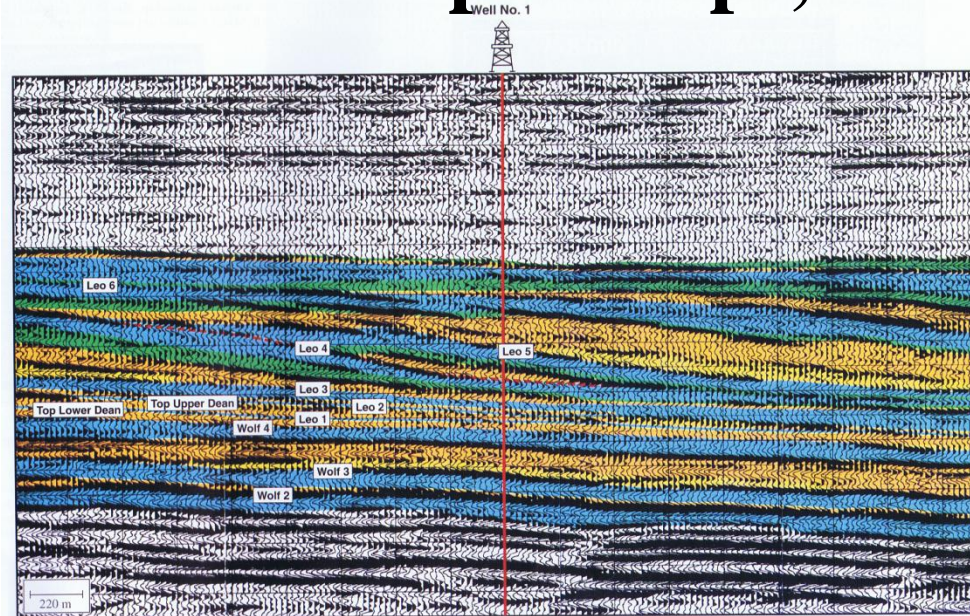

The Interactive environment can aid the interpretation of this types of geology by allowing the interpreter to:

1. Locate subtle folding and faulting by expanding the display size with either pixel zoom or interpolation between traces or time samples.
2. Display different types of sections created from the same seismic traces; such as instantaneous phase to enhance reflection continuity; instantaneous frequency to look for frequency tuning or absorption; reflection strength to look for amplitude anomalies; stacking velocity to look for velocity anomalies; acoustic impedance to look for temporal or spatial lithologic changes; synthetic sections to compare a derived geologic model with actual seismic data; etc.
3. Create paleo-time-slices to evaluate spatial variations in the different types of data described in 2 above. These sections are created by extracting the attributes from vertical sections at specific horizon times and mapping.
4. Use softcopy color options to enhance subtle differences in the data, making large displays for detailed study.

# Faulted Anticlines

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

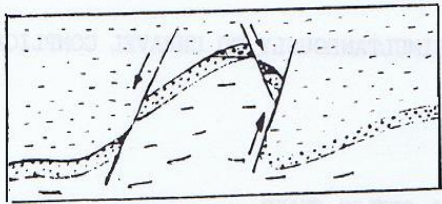

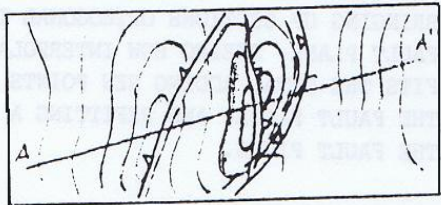

FAULTED ANTICLINES are often associated with faulting due to original folding. These faults frequently form impermeable barriers which divide a structure into separate reservoir pools.

Faulted anticlines occur in a variety of geographic locations and within many different types of structural styles.

The Interactive environment can aid the interpretation of these types of structures by allowing the interpreter to:

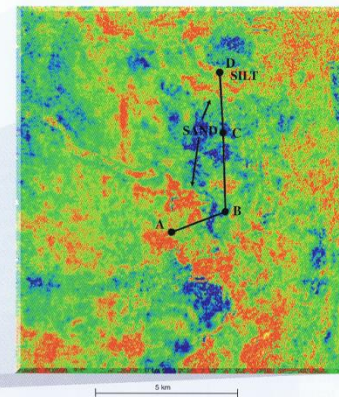

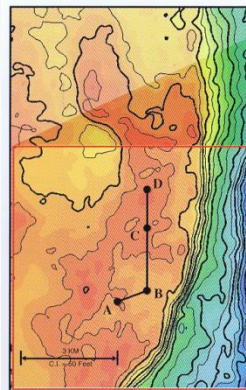

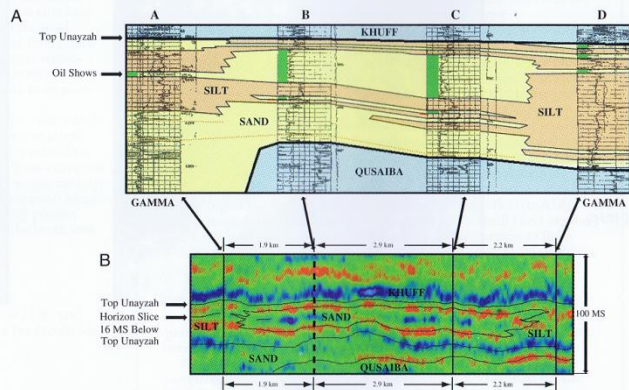

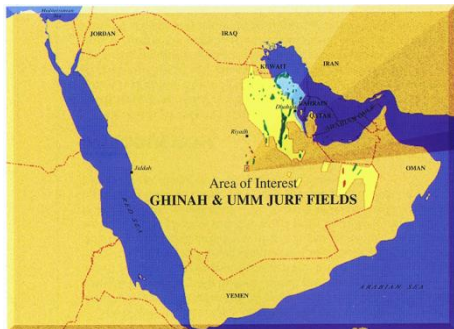

1. Select sections for display orthogonal to the fault heave.
2. Pick faults as a vector list whenever they are recognized on a section, then display all of the picks in the fault database in map view to allow the interpreter to interactively connect fault segments, build fault plane maps, generate fault plane surfaces, and fault heave polygons.
3. Use the fault correlation window to reconstruct geology along polygonal boundaries.
4. Use the drag window to move and correlate a third window of data across faults.
5. Flatten the seismic on specified horizons to check the relative throw in different fault blocks. If there are busts in fault blocks, the reflection packages will not tie.

6. Work back and forth with the horizon display and the seismic section display to identify fault trends, anticlinal plunge, dip direction, critical closures, etc.

# Antithetic or Synthetic Faults

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

ANTITHETIC or SYNTHETIC FAULTS are tensional faults that cut rollover anticlines as they form, often dividing hydrocarbon reservoirs into numerous pools. These type of traps are particularly common among the growth faults and salt domes of the Gulf of Mexico and West Africa.

GENERALIZED MAP

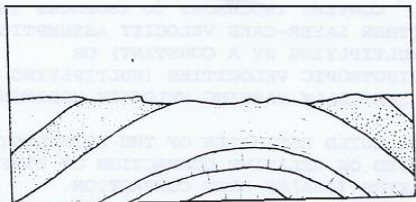

GENERALIZED CROSS-SECTIONS

The Interactive environment can aid the interpretation of these types of structures by allowing the interpreter to:

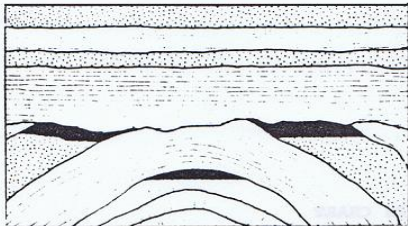

1. Use the computer to build and keep track of the fault data base as described in **FAULTED ANTICLINES**.
2. Recognize antithetic vs. normal faults by moving a color marker through a map display of all fault times. On normal fault planes the marker will always move in the same direction, and it will move opposite on the first antithetic times and back in the normal fault direction on an **ANTITHETIC FAULT** ending into **ANTITHETIC FAULT**.
3. Create fault plane maps by identifying fault segments that belong to the same fault, labeling them as a specific fault, and fitting a surface to the specified points
4. Check and modify fault hypothesis by bring up sections orthogonal to the fault plane, seeing how interpolated faults fit the data, adding new points to improve the fault planes, and refitting a surface to the fault picks.
5. Use the polygon and drag windows to reconstruct fault blocks.
6. Work with both map and seismic displays simultaneously to unravel complicated geology.

# Bald Headed Anticlines

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

EROSION OF DOME STRATA, TRUNCATING POROUS SANDSTONE BED

SHALE DEPOSITION OVER THE UNCONFORMITY SEALING THE POROUS BEDS AS A TRAP

RENEWED UPLIFT DEFORMS BEDS ABOVE THE UNCONFORMITY CREATING ADDITIONAL RESERVOIRS

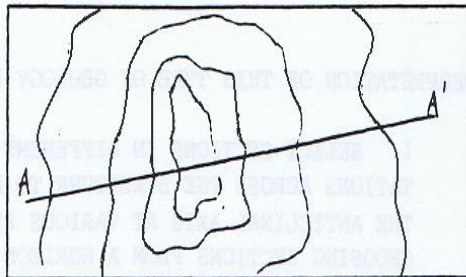

BALD HEADED ANTICLINES develop in stages, as shown in the cartoon below (from **Geological Evolution of North America**, p. 274, R.L. Carroll and T.H. Clark, Publisher John Wiley & Sons, 1979).

The Interactive environment can aid interpretation of this type of geology by allowing the interpreter to:

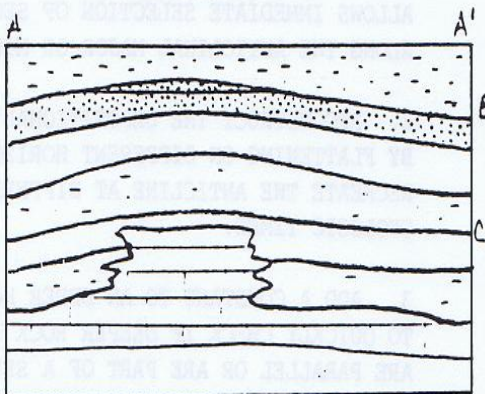

1. Select sections in different orientations across the structure to determine the anticlinal axis at various levels. Choosing sections from a horizon that is extracted amplitude at a specific time allows immediate selection of sections along the anticlinal major or minor axis.
2. Reconstruct the depositional history by flattening on different horizons to recreate the anticline at different geologic times.
3. Add a constant to an upper horizon to quickly check if deeper rock layers are parallel or are part of a separate stratigraphic sequence separated by an unconformity.
4. Display a shallower horizon as multiple contours on a surface (raster) display of a deeper horizon to study differences in the relative dip of the two horizons on a single display.

# Compaction Anticlines

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

GENERALIZED MAP

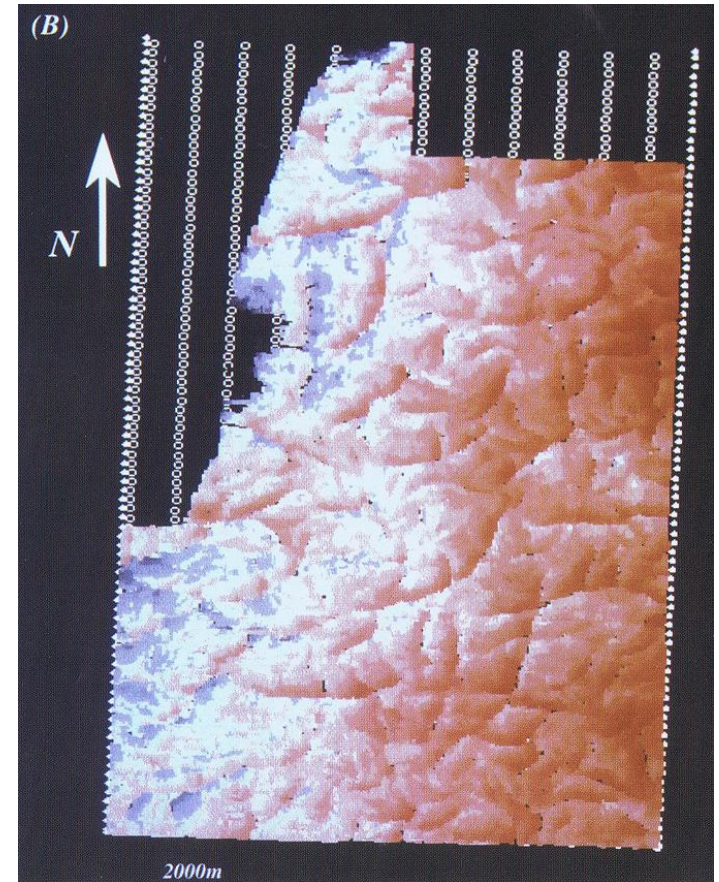

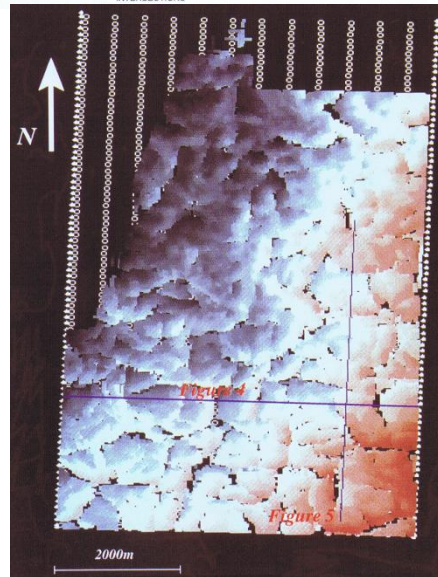

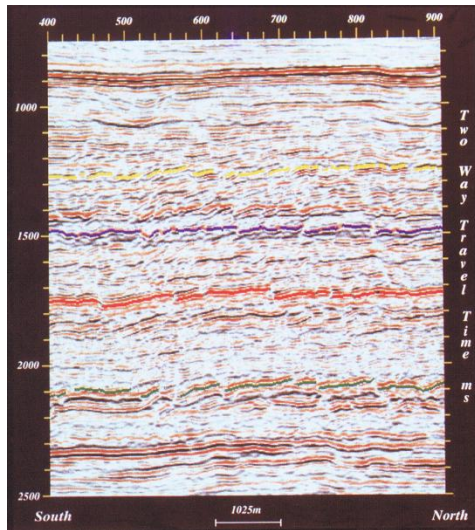

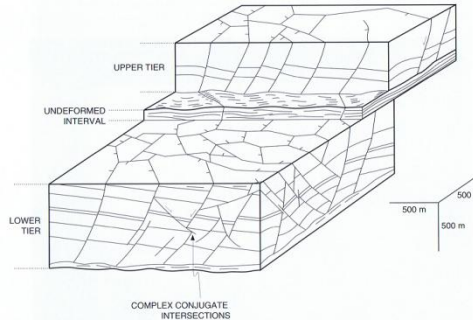

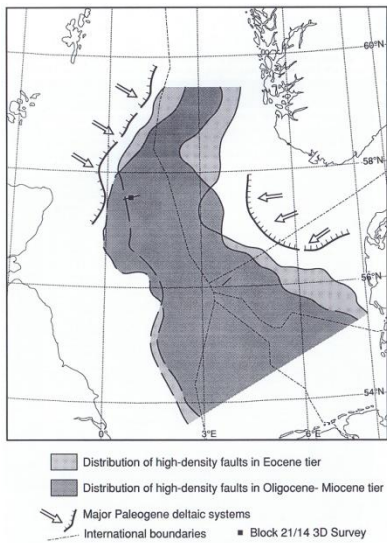

GENERALIZED CROSS-SECTION

COMPACTION ANTICLINES are structures occurring over buried hills and reefs. The overlaying sediments compact more than the basement hills and limestone reefs creating anticlines. The sediments on the flanks of the controlling structure create additional compact. The generalized map below could be a time structure map showing dip off the anticline, or an isochron map showing thickening between reflectors from B and C off the structure. The Interactive environment can aid interpretation of this type of geology by allowing the interpreter to:

1. Study the relative amount of compaction during different geologic times by flattening on different horizons and measuring the time to a deeper reflector by using the show location option.
2. Use map displays with multiple contours on surface displays to study the relationship between different horizons, isochrons, and the amount of compaction.
3. Convert isochrons to isopachs with layer-cake or anisotropic velocity assumptions.
4. Build estimates of the lithology based on relative compaction of different layers (shales most compaction, carbonates least, and sands in the middle).

# Polygonal Fault Systems

## North Sea Basin

Joseph A. Cartwright in **Application of 3-D Seismic Data to Exploration and Production**, pages 227, 229-230, data from Fina Exploration Ltd., Texaco U.K. Ltd., Santa Fe Ltd., and Purbeck Oil & Gas Ltd. In Block 21 / 14b

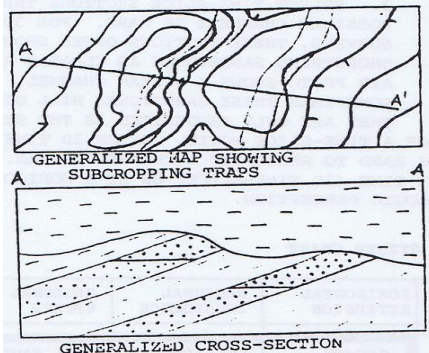

# Angular Unconformities

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

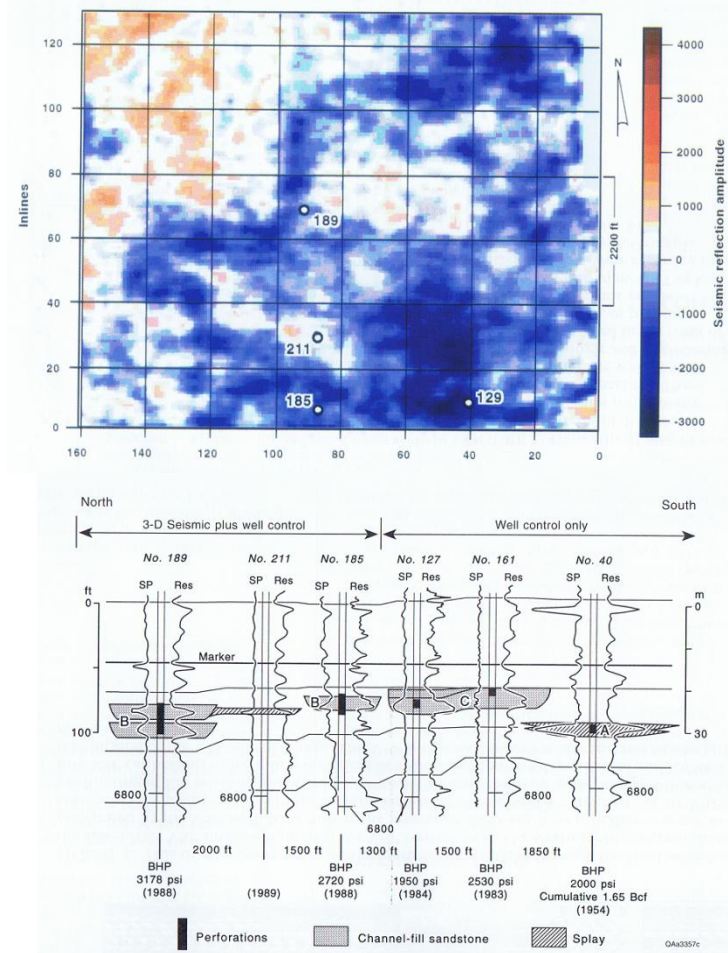

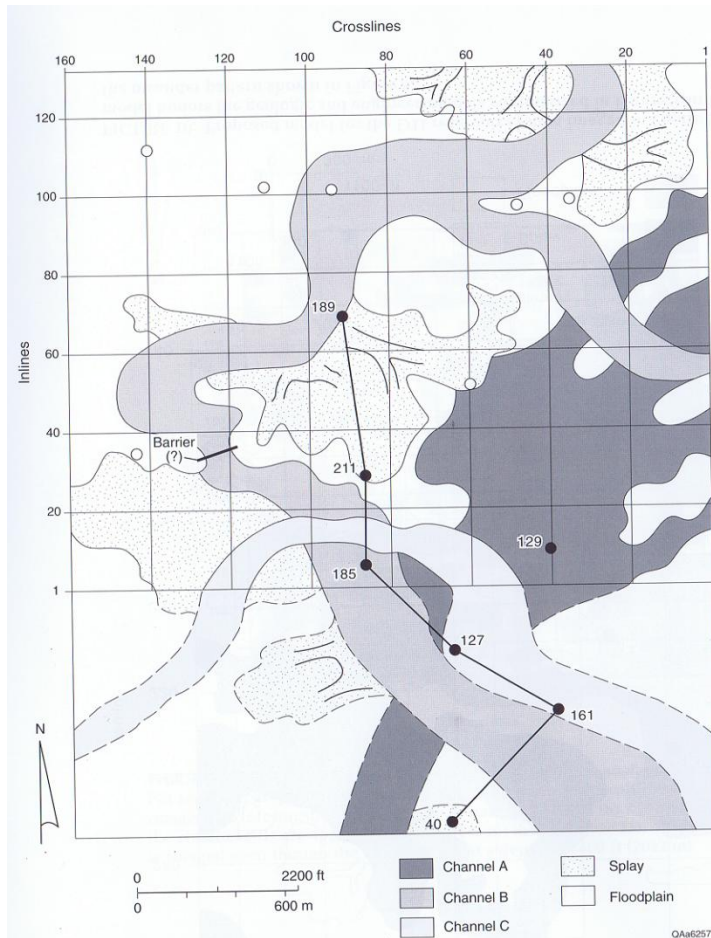

ANGULAR UNCONFORMITIES occur where dipping rocks come up against a buried erosional surface. This type of stratigraphic trap is very widespread and occurs in most basins around the world. Many of the giant North Sea fields are angular unconformities, where the Jurassic or Base Cretaceous is the trap. The Statfjord Field, located on the Norwegian/British demarcation is an example.

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Dynamically scale the data to enhance the strong reflector from the unconformity, or clip the strong reflector to enhance the weak trapping reflectors underneath.
2. Build instantaneous phase sections to increase reflector continuity and improve picking of weak reflectors.
3. Do post stack reprocessing to improve critical reflectors: such as predictive or spiking deconvolution to cut out multiples or interbed ringing, filtering to enhance a certain frequency range, or wavelet substitution to match different vintages of 2D data.
4. Use amplitude extraction to study subtle changes in reflection energy and thus the reflection coefficient at the unconformity horizon.
5. Add a constant to the unconformity and extract amplitudes to study subcropping events. Paleo-time-slice movies beneath an unconformity often show subcropping events better than regular time-slice animations.

# Thin-Bed Fluvial Reservoir Interpretation

Bob A. Hardage, et. al. in **Application of 3-D Seismic Data to Exploration and Production**, pages 30-31, Stratton Seismic data from the Texas Bureau of Economic Geology.

# Shoestring, Channel, Bar Sandstones

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

SHOESTRING SANDSTONES are long, narrow sand bodies formed by channels or bars. These stratigraphic traps are often encased in shale and filled with oil with no oil water contact.

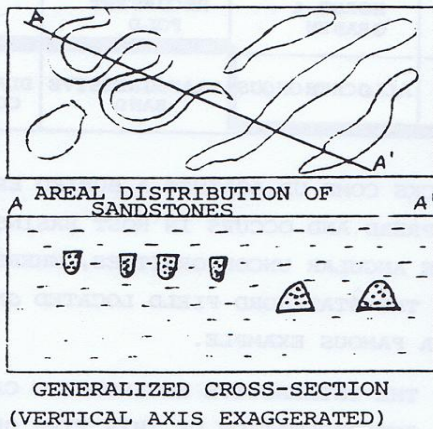

CHANNEL SANDSTONES are from meandering river channels or delta distributing channels.

BAR SANDSTONES are from beaches or destructive deltas and the associated offshore bars. Bars are differentiated from channels in cross-section (🏖️ or 🏰), orientation (parallel to the shoreline vs. perpendicular), and the vertical sequence (coarsening upward vs. channel filling upward) [After Dr. N. J. Hyne, **Oil & Gas Field Classifier**].

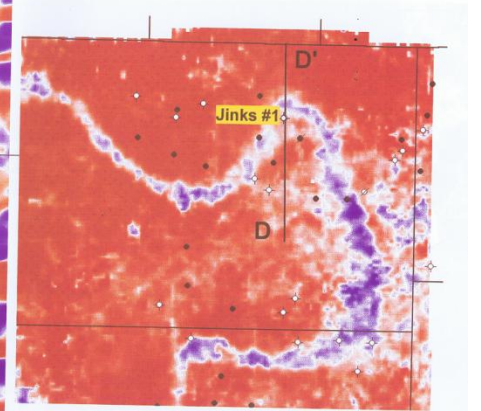

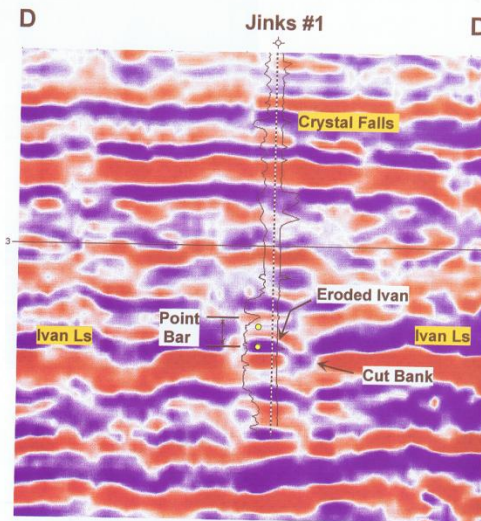

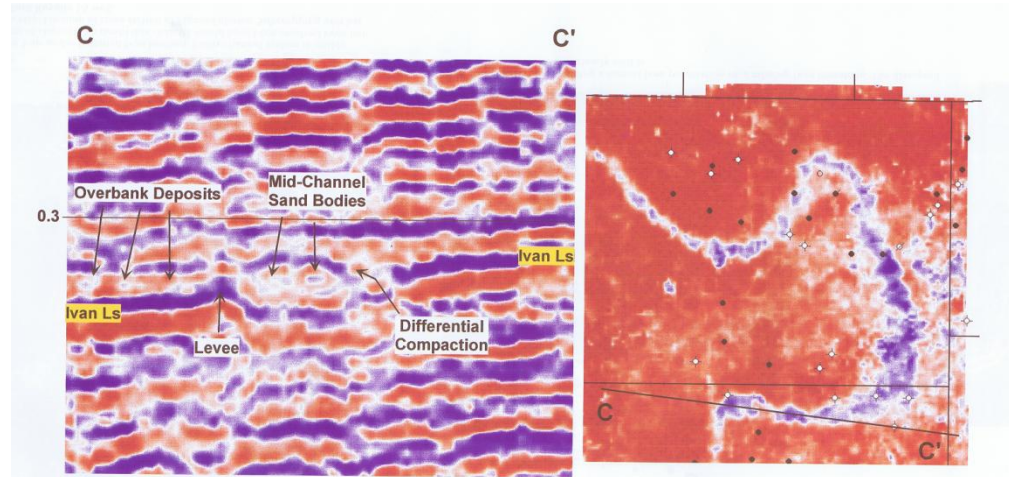

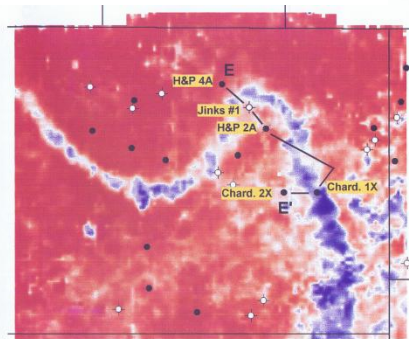

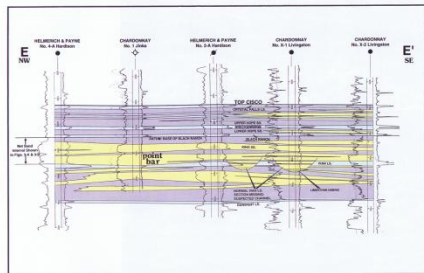

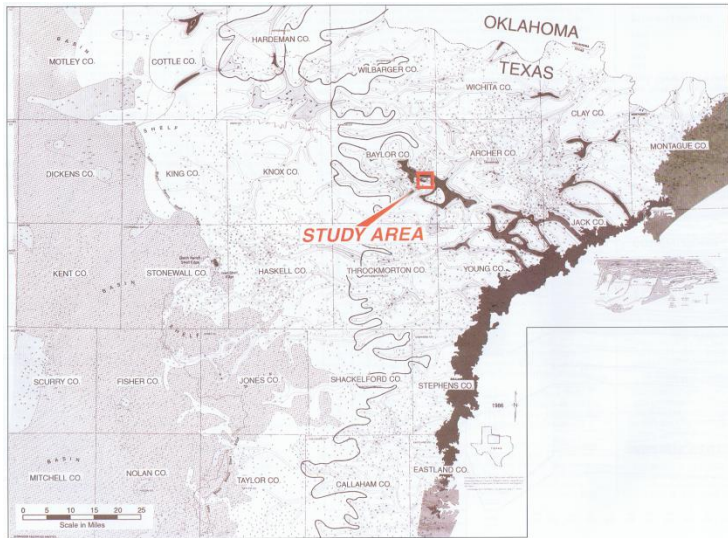

The Interactive environment can aid the interpretation of

this type of geology by allowing the interpreter to:

1. Manipulate the display colors so as to enhance diffractions or reflection continuity changes due to channel cuts or bar buildups of sandstones.
2. Select traces cutting through (dip) or following along (strike) SHOESTRING SANDSTONE or other elongated sandstone bodies.
3. Select time-slice sections through possible channels or bars. For 3-D surveys, these sections often show ancient shoestring sandstones as clearly as an air photo shows a stream channel. Sometimes these sandstones will dip and they are only recognized as the eye integrates animation frames. Often 2-D time-slices are spatially aliased making it hard to recognize a channel or bar. Gridding helps.

# Overbank, Channels, and Point Bars

# Stratal Slices

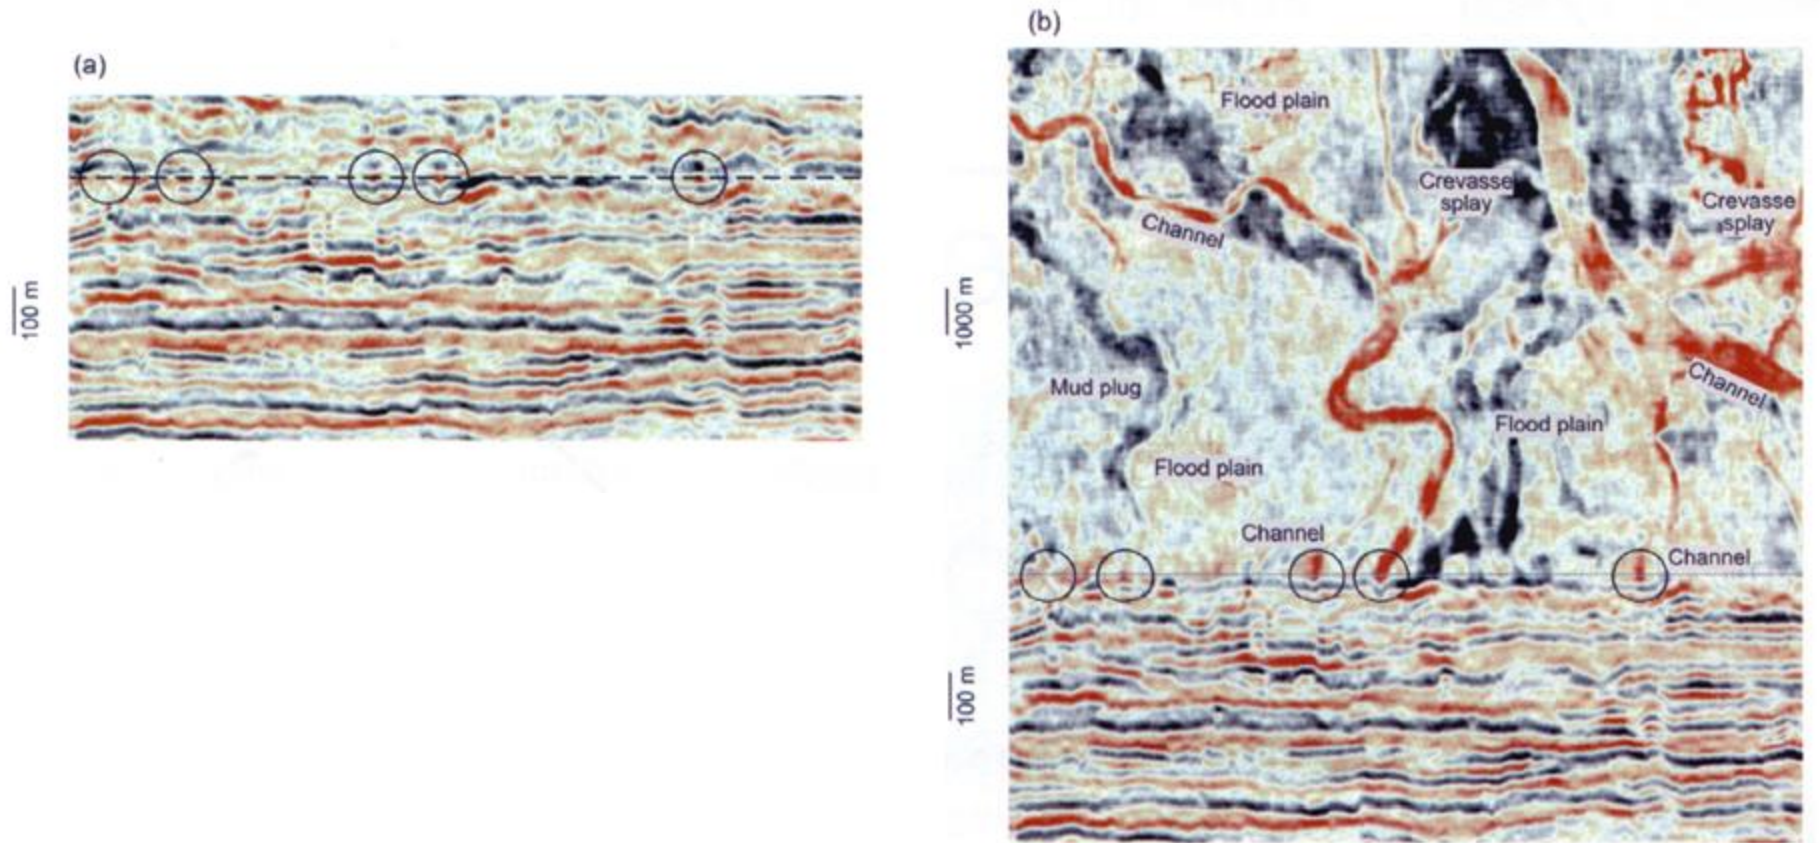

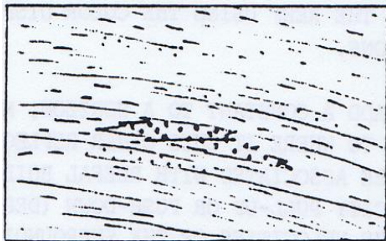

Figure 1. (a) Vertical section view of a fluvial environment (dash line and circled features); (b) Stratal slice showing small depositional features are better seen in horizontal view than in vertical view.

A. Hongliu Zeng, The Bureau of Economics Geology (BEG), 1996, Stratal Slices.

# Oolite Shoals

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

OOLITE SHOALS are made of sand-sized spheres of CaCo which has precipitated out of shallow tropical seas and has been washed into elongated mounds by waves. These stratigraphic traps form small fields, and many shoals often parallel each other. N.S. Neidell has shown the value of color, acoustic impedance, and detailed velocity analysis to enhance recognition. [Neidell, et. al., Improve Prospect Picks with Move Out Velocity Analysis, **World Oil**, pages 129-142, January 1984.] The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

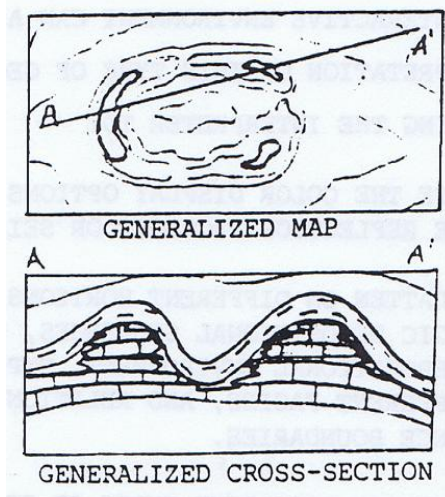

GENERALIZED CROSS-SECTIONS

1. Use the color display options to enhance unique reflection packages or seismic facies.
2. Flatten on different horizons to reconstruct geologic depositional sequences, estimate the depositional environments, types of sediments, and tie to sequence boundaries.
3. Display different types of sections to enhance an anomaly temporally and spatially, like Hilbert Transform attribute analysis, velocity, or acoustic impedance sections.
4. Use horizon display and map select options to study the relationship between similar anomalies, like parallel elongated mounds with similar reflection character.
5. Look for tel-tale anomalies associated with hydrocarbons, like flat spots associated with a gas/water contact, amplitude anomalies, etc. If these events are recognized, the basic steps of calculating net producible gas sands can be followed, i.e. make the data zero phase, pick a peak and trough through a bright spot, calculate isochrons, extract amplitudes, calculate composite amplitudes, smooth, calculate net gas sand isochrons and convert to isopachs.

# Atolls

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

ATOLLS are large, circular or elliptical reefs that enclose a central lagoon. The reef limestones form good reservoirs, but the fine grained lagoonal limestone does not. There are numerous modern day examples of this type of reef development around the world, particularly in the SW Pacific Ocean.

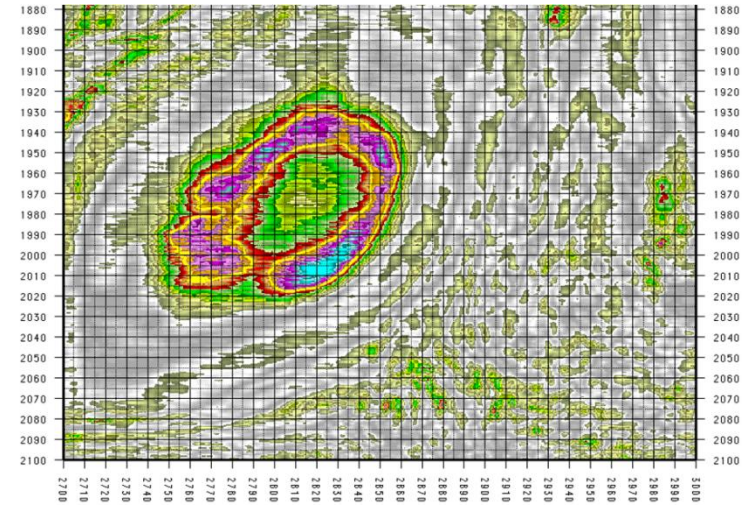

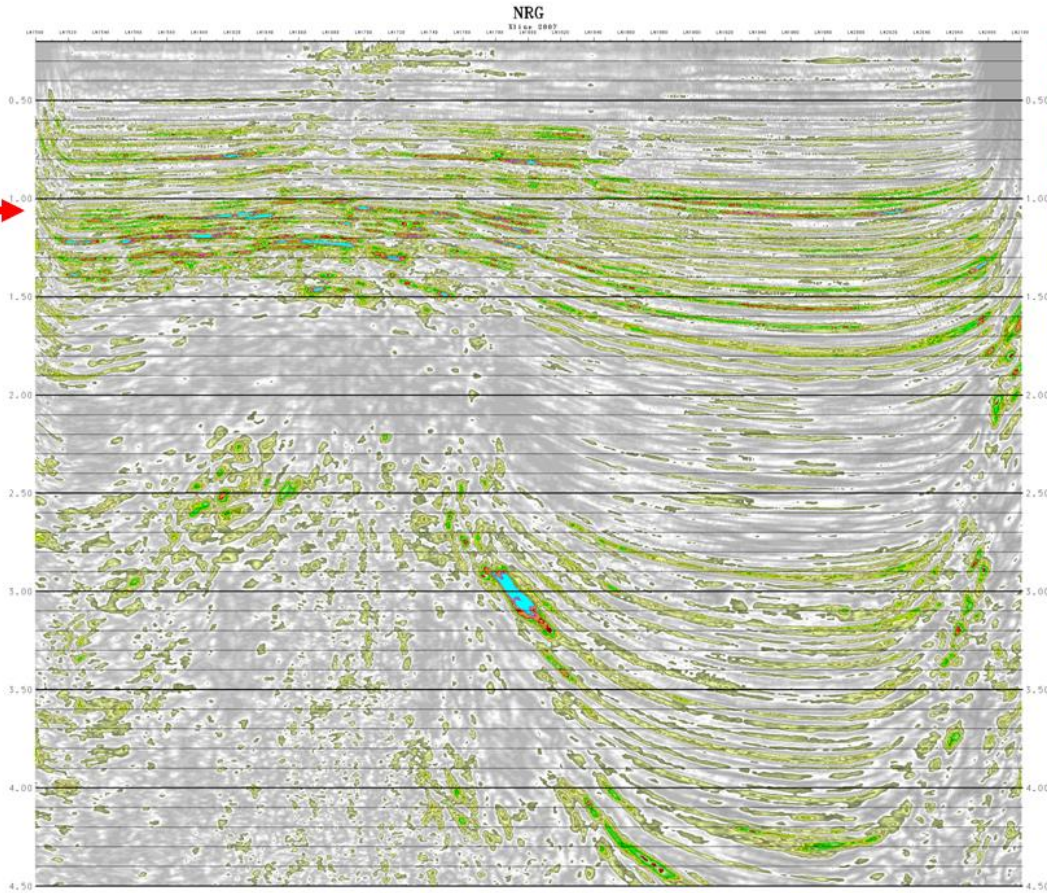

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

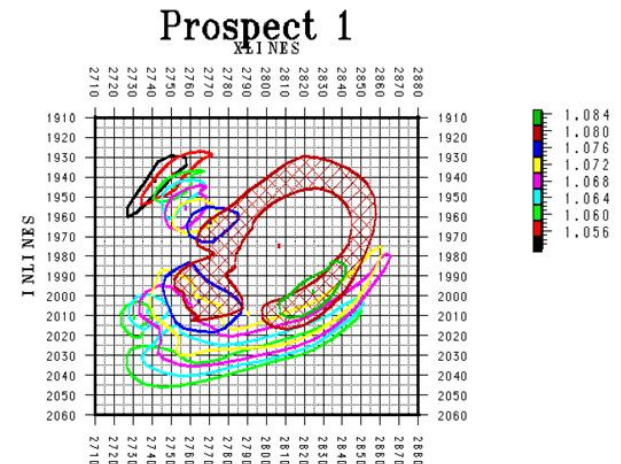

1. Enhance reflection anomalies associated with the reef using color display options.
2. Add a constant to a horizon, moving it down to where it cuts other reflectors that can be associated with reefal buildup, velocity pull-down or push-up (depending on the velocities of the surrounding rocks), diffractions, etc.
3. Time-Slice sections, which are particularly useful in studying reef build-up, like those associated with an ATOLL. For 3-D surveys, these time-slices can be created at constant time or parallel to a horizon or proportional to expanding sections. These same options are available for 2-D surveys by extracting amplitudes appropriately.

4. Work back and forth between map and section displays to look for reef trends on a regional basis, along a play fairway, or specific reef configurations at a lead or prospect basis.

# Pinnacle Reefs, Patch Reefs, & Bioherms

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

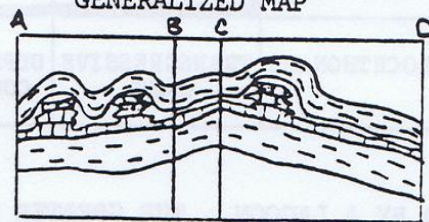

PINNACLE REEFS are small, circular reefs on the basin side of a barrier reef. PATCH REEFS typically occur in a lagoon. BIOHERMS are mounded or lens shaped deposits of biological organisms, both non-framework and framework organisms like corals. These three types of traps tend to produce small fields. Bioherms are more isolated. PINNACLE and PATCH REEFS are usually numerous along trends in several parts of the continental U.S., including Michigan.

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Plot trends on a regional basis and do detailed analysis of each local anomaly by zooming in or expanding the display scales.
2. Use these trends and local anomalies as the basis for high grading potential prospects. This might result in doing additional post-stack processing, collecting more densely spaced 2-D lines, or even a small 3-D survey, detailed modeling, etc.
3. Study the effect of variations in amplitude with offset through anomalies of interest. A single line through a reef can be loaded as a 3-D seismic survey where the 3-D axis are CMP, offset, and two-way travel time. Movies through this data show amplitude variations as a function of CMP, offset, time, or stacking velocity (extracted amplitudes parallel to reflector picks).

GENERALIZED MAP

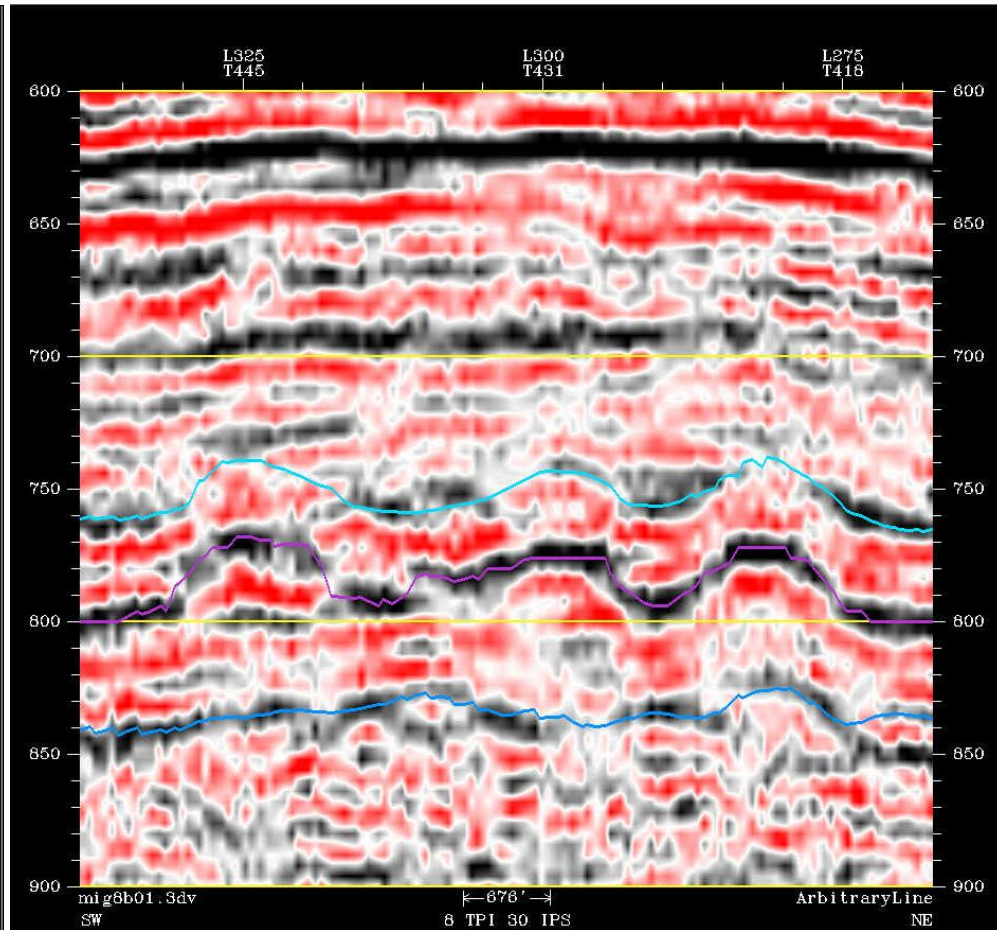

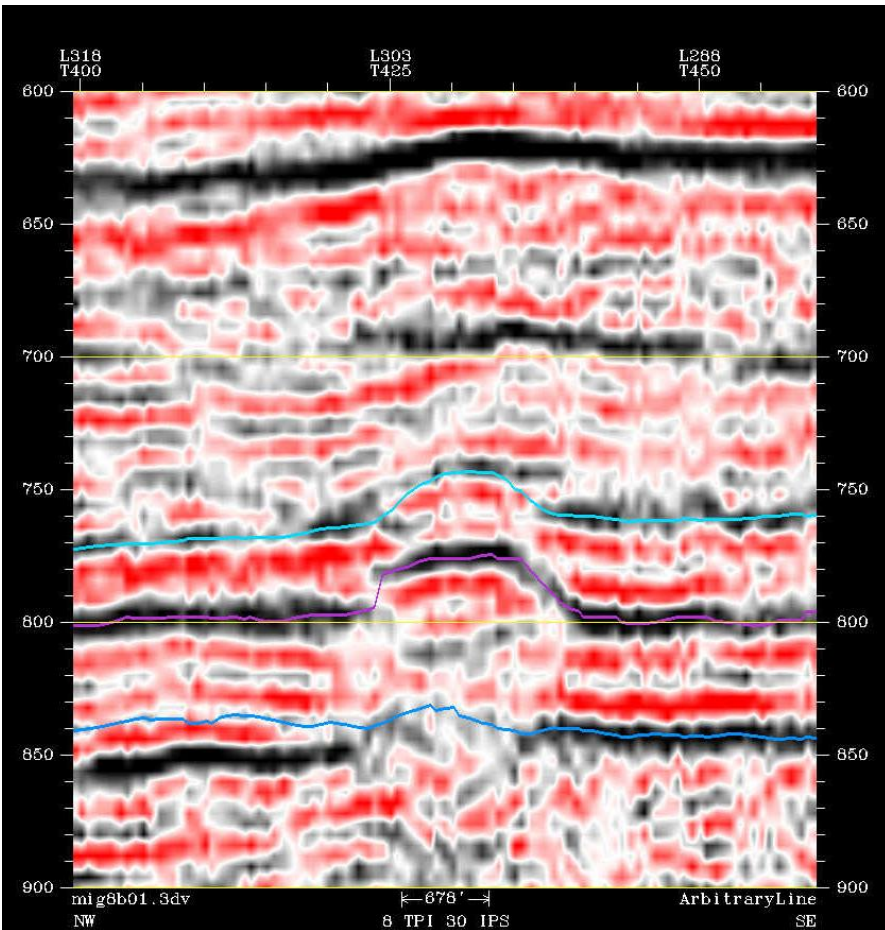

GENERALIZED CROSS-SECTION

4. Work back and forth between map and section displays to do detailed analysis and look for regional trends.

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

**BARRIER REEFS** are large reefs separated from land by a lagoon. The Great Barrier Reef of NE Australia is a modern day example of this type of reef. The flat, layered limestones are typically good reservoir, but the lagoonal micrite limestones are not. Of course, there can be later porosity reversals due to later recrystallizations, solution vugs, and dolomitization. Reefs form the traps for many of the oil fields in Alberta Canada, including the famous Leduc Reef with fist sized pores.

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Interpret (pick and map) as many horizons as necessary to identify anomalous material buildup, and the lateral extent of that buildup.
2. Do detailed studies of the reflector characteristics, including: filtering, attribute studies, wavelet processing, etc. to determine the extent of the framework based limestones and the beginning of the tight micrite limestones. Detailed studies of wave form changes can be related to hydrocarbon fill, facies changes from bedded limestones to coral reef carbonates to lime sands to argillaceous limestones to course-grained dolomites. Of course, seismic can not specify all lithologies yet.

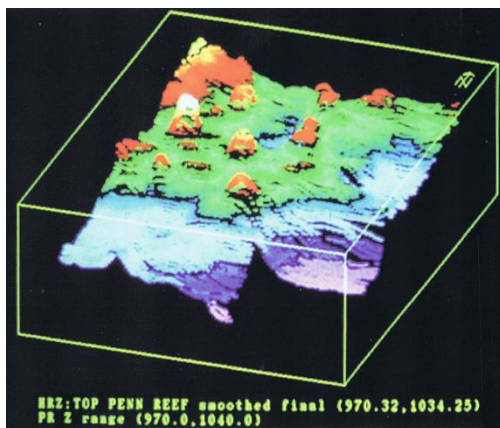

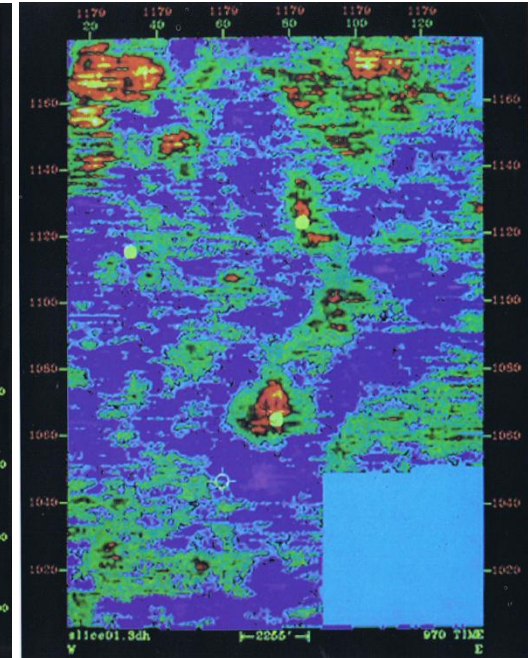

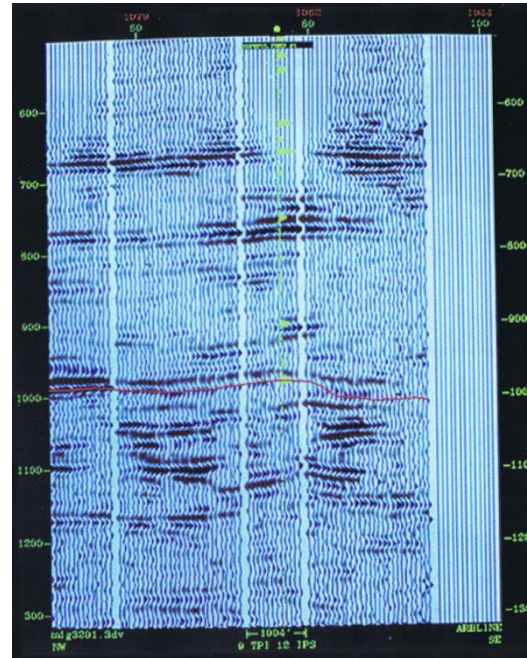

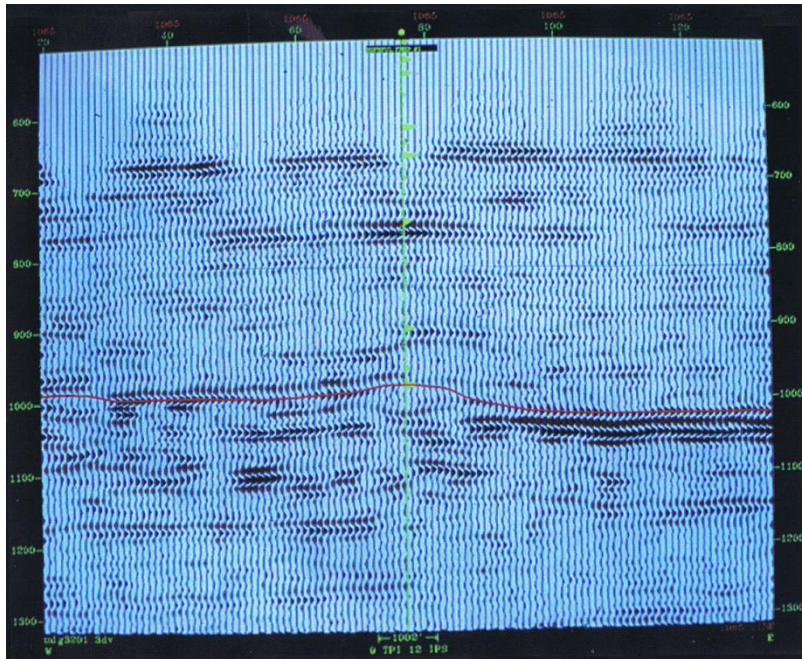

GENERALIZED CROSS-SECTION

3. Extract amplitudes in order to study spatial variations of the reflection strength. As with pinnacle reefs and bioherms, time-slice or paleo-time-slice sections can show the areal extent of anomalies of interest.

# Primary and Secondary Dolomite

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

PRIMARY and SECONDARY DOLOMITE reservoirs are formed by the alteration of limestone in those areas beyond the tides immediately after deposition. These traps are often overlaid by a salt layer. Many of these traps can be located along basin flanks due to changing water levels.

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Evaluate lateral variations in reflection strength or other attributes calculated from the seismic to attempt to recognize the areal extent of dolomitization.
2. Post stack process the data, particularly emphasizing lateral variations in high frequency information by using a high-pass filter, and possibly by calculating the instantaneous frequency.
3. Use horizon flattening and the location of the cursor to measure the interval time differences along a layer, as a tool in identifying the lateral extent of overlaying salt layers which might have affected dolomitization.
4. Work back and forth between map and section displays to build trend maps and accurately evaluate the areal extent of anomalies of interest.

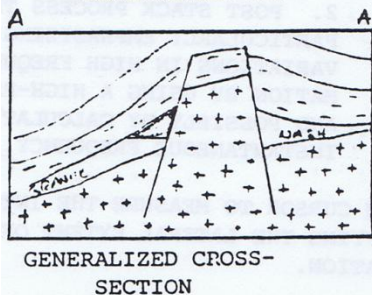

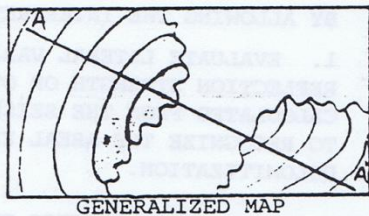

GENERALIZED CROSS-SECTIONS

# Granite Wash

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

A GRAITE WASH forms from weathering of a granite basement, such as in an alluvial fan formed at the mouth of a canyon cut through a granitic uplift. These types of granitic washes can be studied today in the basin and range province of the Rocky Mountains, where they cover the flanks of buried granite mountains and hills. Hydrocarbons come from source rocks deposited deeper in the basin. In the general example below, the basin to the southeast does not have source rocks at depth.

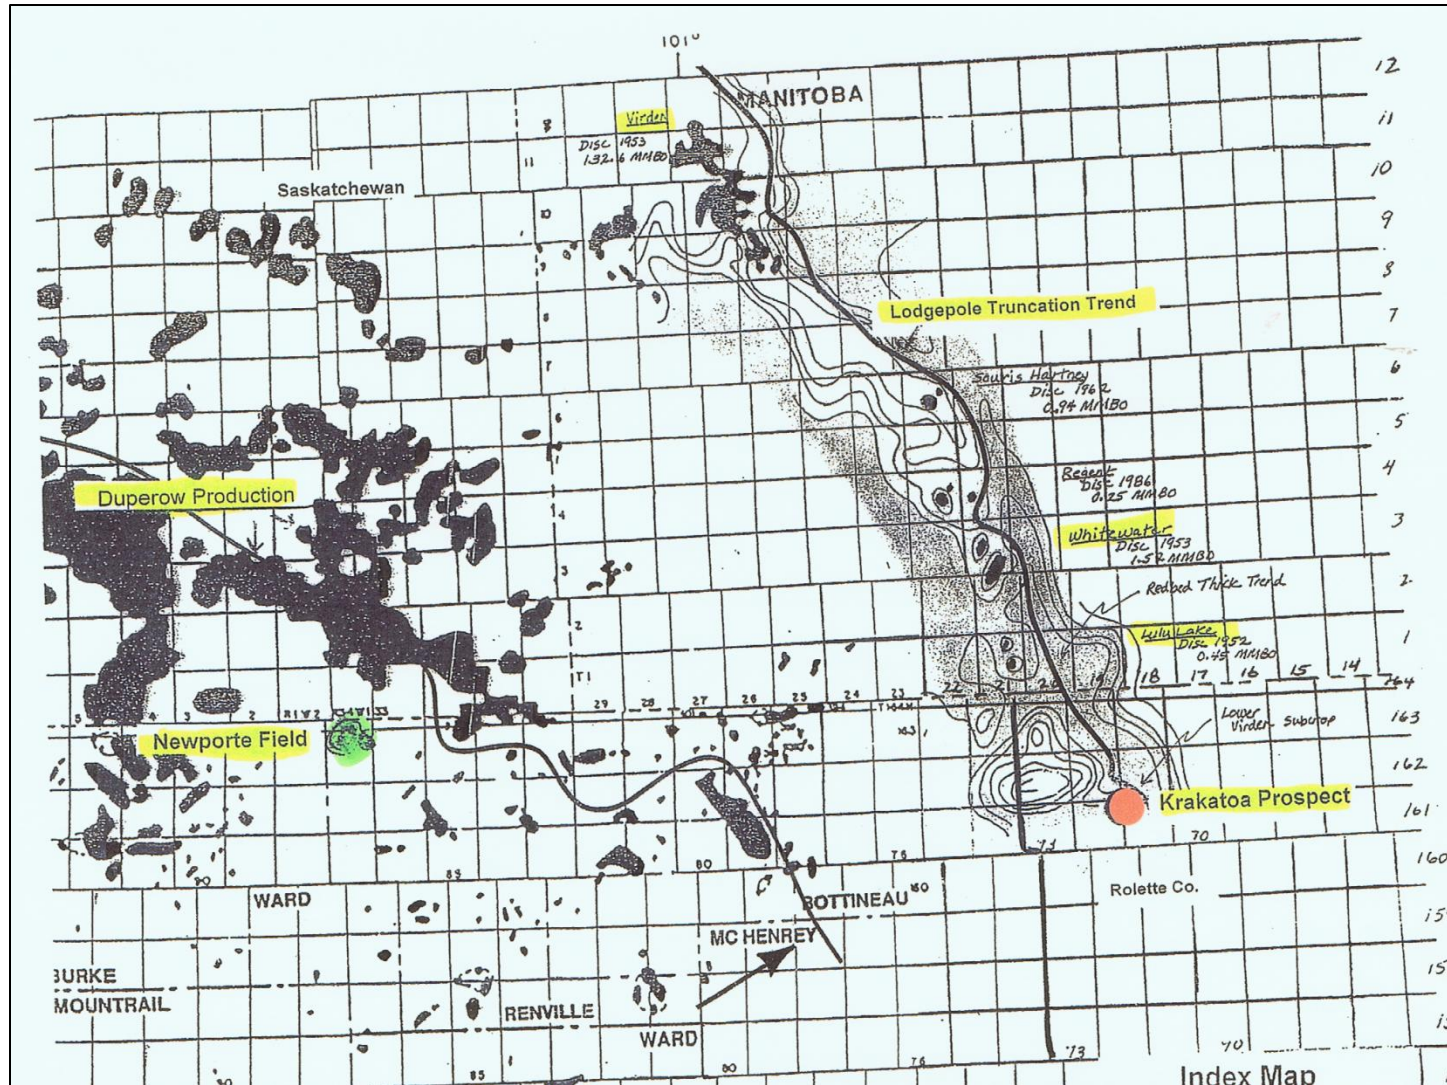

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Map the sequence boundaries defining the alluvial fan and compare them to time and depth maps of basement reflector(s).
2. Reconstruct pre-unconformity geology by flattening basement horizons or using the polygonal fault correlation window. This paleogeologic picture can be used as a basis for determining the origins of a supposed granitic wash.
3. Evaluate the potential for downdip source rocks by using the arbitrary line option in 3-D surveys and zig-zagging to critical source basins with a 2-D survey.
4. Work back and forth between the horizon map and the sections to build an accurate geologic picture of the study area.

# Buttress or Onlap Sands

Tectonics Basement	Horizontal Compression	Differential Vertical	Horizontal Extension	Regional or Basin Subsidence	Regional Upward
Detached	Thrust	Domes	Growth	Collapse	Dip & Fault
Involved	Reverse	Drape	Horst & Graben	Recumbent Fold	Arch
Weak	Strike-Slip	Decollement	Allochthonous	Transgressive Sand	Differential Compaction

BUTTRESS or ONLAP SANDS are beach sands deposited on an unconformity surface as the sea level rises. There can be numerous of these sands along a single unconformity. This type of hydrocarbon trap can be as geographically widespread as angular unconformities.

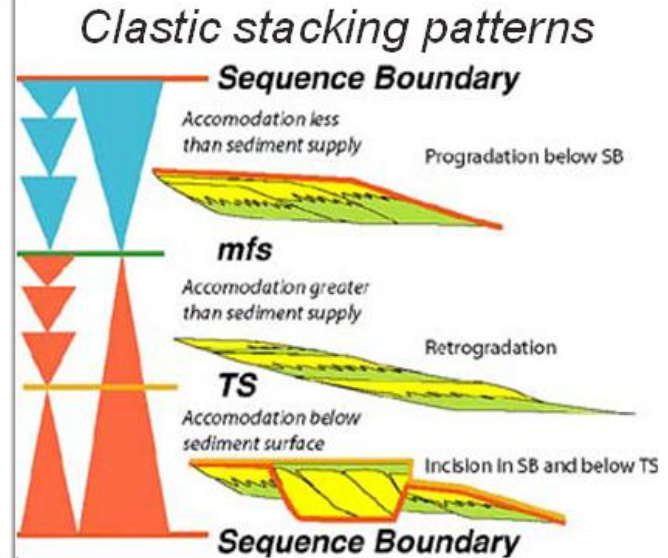

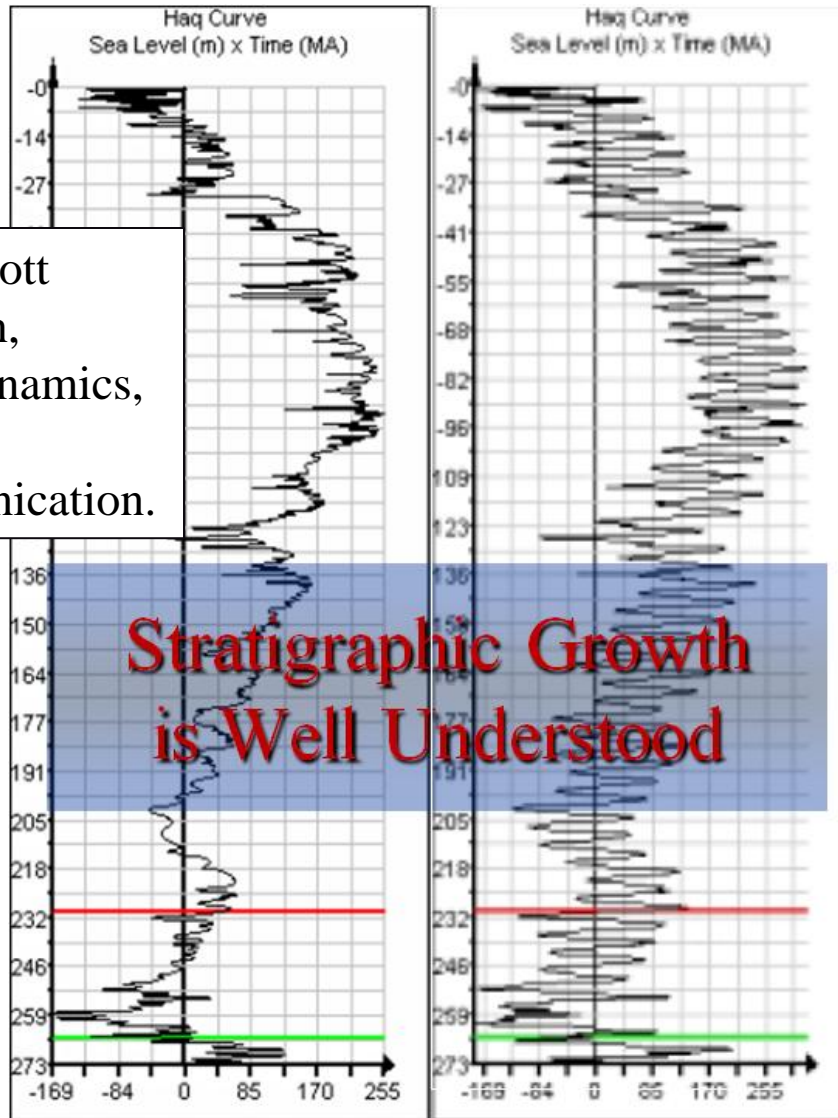

The Interactive environment can aid the interpretation of this type of geology by allowing the interpreter to:

1. Identify and mark different seismic sequence boundaries by creating unique horizons for each boundary.
2. Do detailed study of the reflection characteristics of onlapping sequences of sand shales. Wiggle trace display options allow detail evaluation of the seismic waveform, and, of course, these wiggle traces can be overlain on information intensive variable density sections.
3. Do amplitude extraction at the unconformity horizon, showing variations in seismic reflection energy associated with different types of onlapping sands and shales.

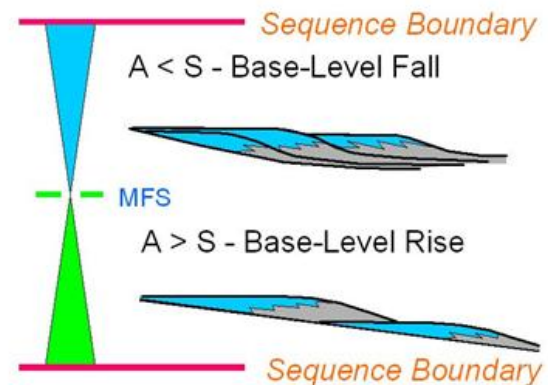

3. Study standard direct hydrocarbon indicator characteristics. These include bright spots (direct hydrocarbon indicators), phase reversals at bright spot boundaries, possibly frequency absorption, amplitude variations with offset, flat spots associated with gas/water contacts, velocity push-downs, etc.

# Salt Interpretation

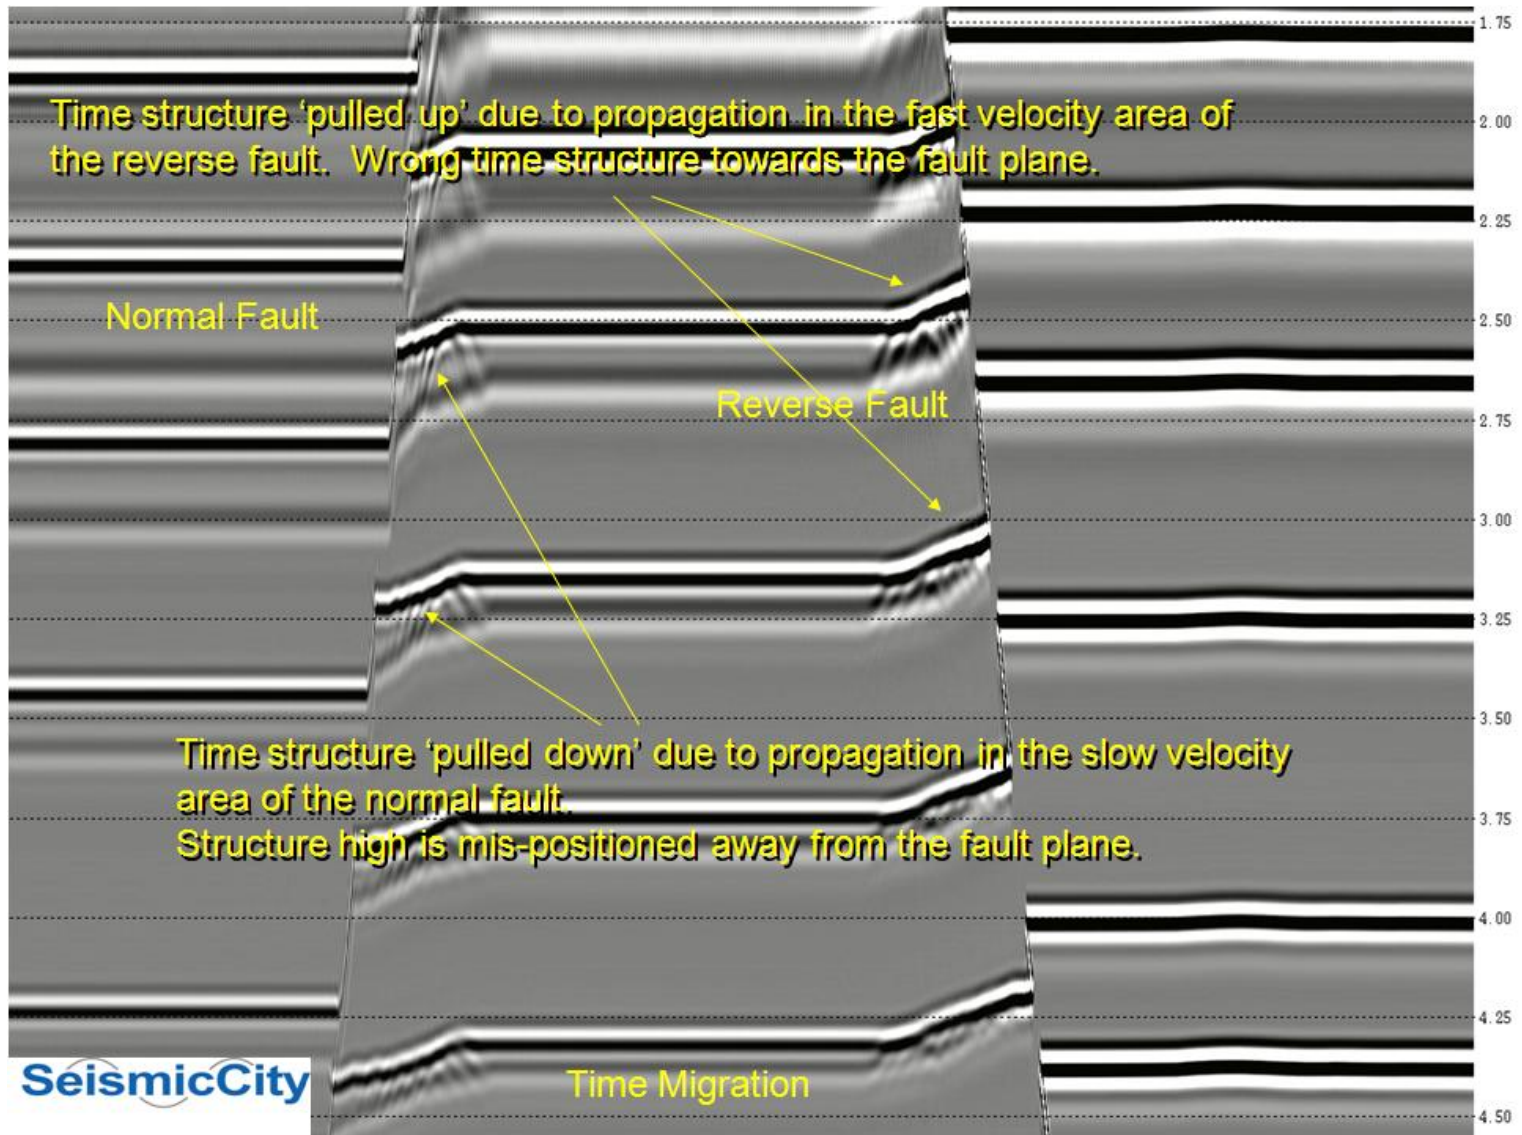

# Fault Shadow Modeling

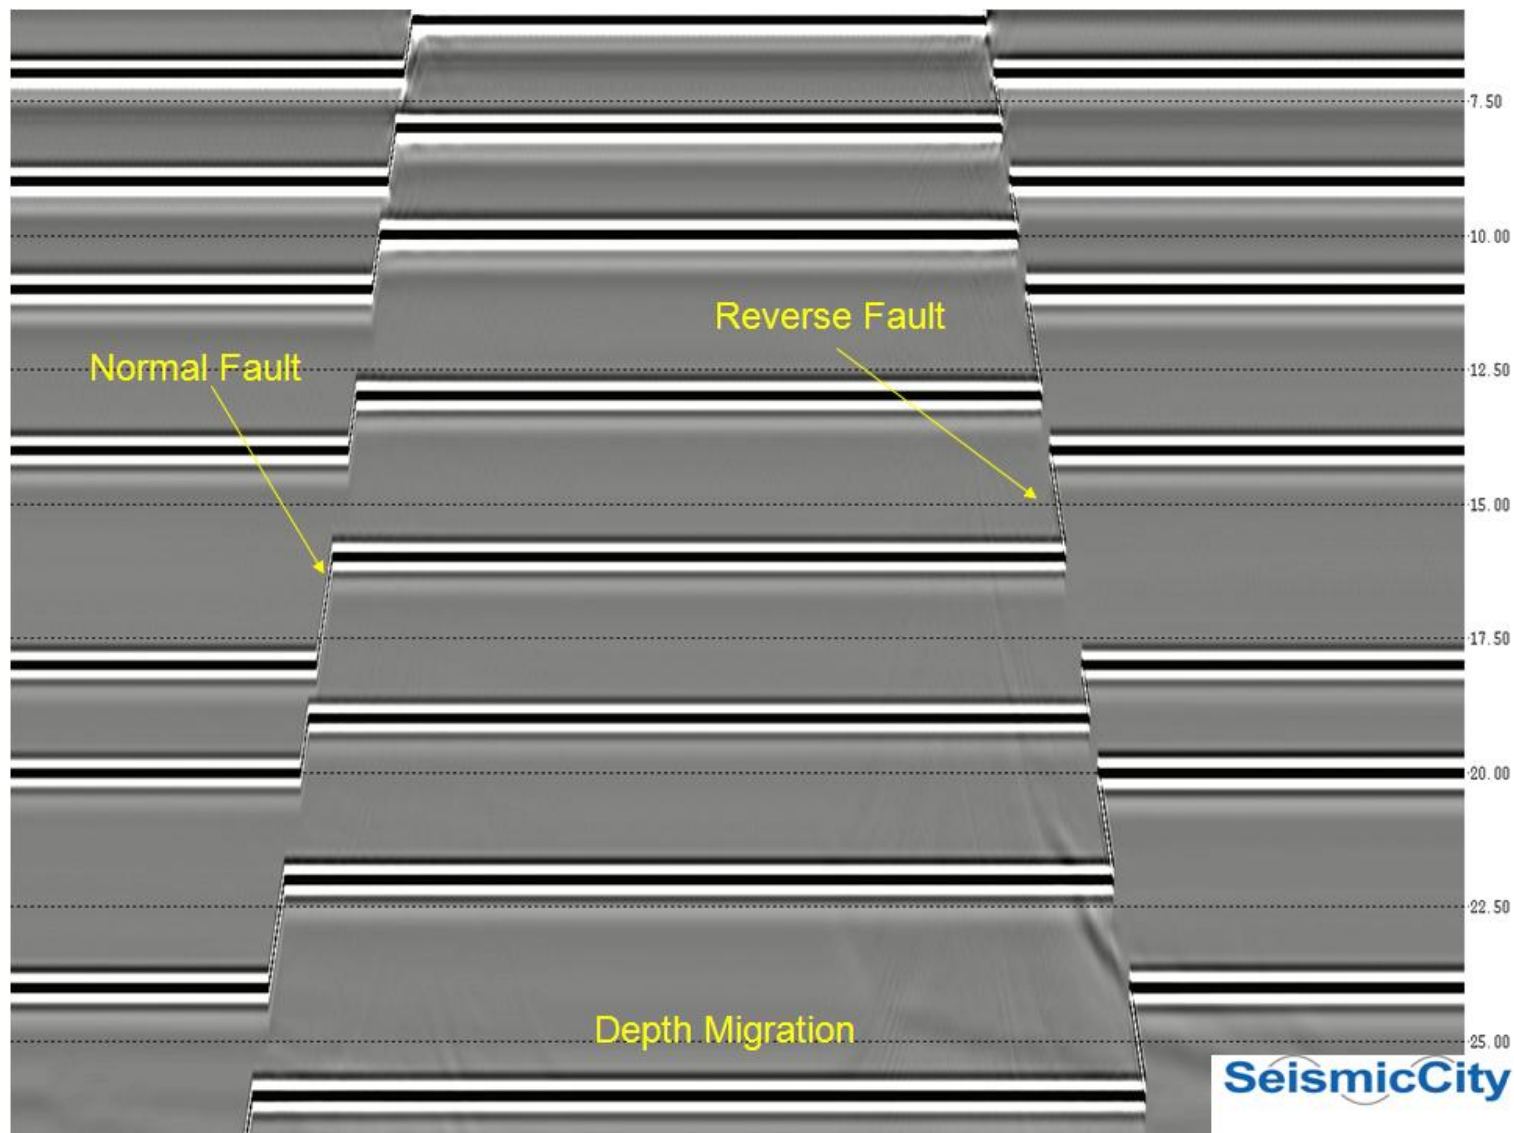

# Fault Shadow Modeling

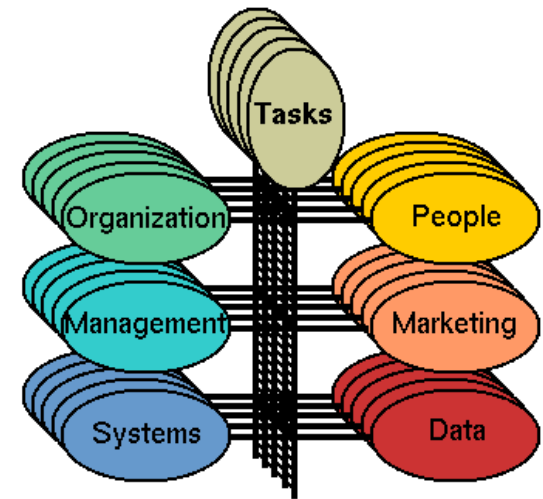

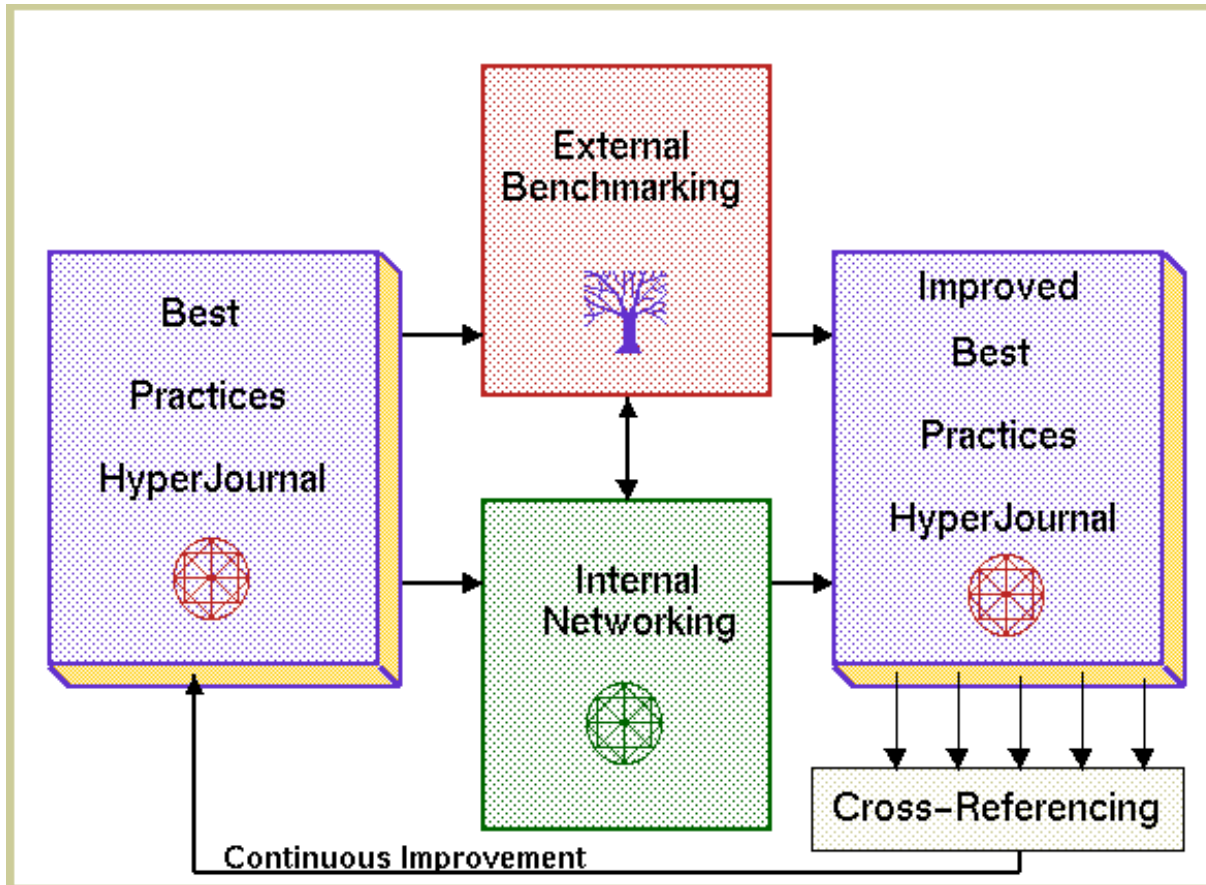

# Fault Shadow Modeling

# Fault Shadow Modeling

# Project Documentation

Linked Indexed Experience  
Becomes Available to All  
Authorized Users.

Automation of documentation, indexing, and availability through a standard Browser allows improvement and Knowledge Capture.

# Pre-Program Questionnaire

- How does interpretation workflow optimize documentation, visualization, and presentation?
  - How do seismic velocities impact seismic interpretation?
  - What is the impact of fault shadows on seismic interpretation?
  - What are other key seismic interpretation pitfalls?
